THE PROPER EMPLOYMENT OF PREPARED FOODS FOR INFANTS.

BY VICTOR C. VAUGHAN, M.D., PH.D.,
PROFESSOR OF PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

THE feeding of infants which for any reason are denied the mother's breast, has been, and continues to be a question of great interest. Even the matter of the selection of a wet-nurse, where both money and opportunity are abundant, is one of the greatest importance, and, as all know, this method of securing nourishment for the child is not free from danger. First, there is often the dread that the nurse will convey to the child some constitutional disease. Then the nurse can hardly be expected to have that watchful solicitude for the child's health which is the peculiar characteristic of its own mother; and the most trusted servants have been found quieting the baby with opiates and even narcotizing it with alcohol. Again, the nurse who offers herself only on account of the demands of poverty, must often leave her own child to be fed artificially, and the question of the importance of infant feeding is only transferred in its application from the child of the mistress to that of the servant. Lastly, in a large number of cases, from want of a wet-nurse, obtainable at any price, or from want of money, the child must be fed artificially.

When the artificial feeding becomes necessary, of what shall the food consist? In this country, at least, we cannot obtain the milk of the ass or even that of the goat, in quantities sufficient to be used by many. I think that all will agree that cow's milk must continue to be the chief source of nourishment for children, and in a recent article in this journal[1] I endeavored to formulate certain rules for the better care of milk. As soon as the consumer demands it, the dealer in milk will conform to those or similar rules. The result of the application of the rules will not be to injure the trade of the dairyman; but the reverse will be true, inasmuch as his milk will be greatly improved in quality and will command a better price.

In the article referred to I urged that no milk should be given to the child sick with cholera infantum or other summer diarrhœas. This prohibition applies to all prepared foods containing milk or to which milk must be added. Recently I obtained all the infant foods I could find in the market, prepared them according to the directions accompanying them, placed them in four-ounce bottles, making a duplicate test for each food, added some of the ferment which I had found would produce tyrotoxicon in milk, and kept the tightly stoppered bottles at a temperature of 38° C. for six hours, then tested the contents of each bottle for the poison, and found it present in every one of them. It should be clearly understood here that the poisonous ferment was added to the foods.

This experiment fulfils the conditions which would exist were a child sick with cholera infantum to be fed with one of these foods; provided always, of course, that my theory as to the causation of this and kindred diseases in children is true. Some preparations of peptonoids and peptones treated in the same manner as the infant foods, failed to develop the poison, at least, in quantities sufficient to be recognized by any chemical test. I may add here, that a similar experiment was made with milk which had been boiled, and in this also the poison was developed. But in the boiled milk to which no ferment was added, as well as in the unboiled milk to which no ferment was added, the poison did not appear, at least within the six hours.

Now, from these experiments I conclude that foods prepared from milk or to which milk must be added, are not suitable for children who are suffering from the summer diarrhœas. Just why the poison should appear in the milk preparations and not in the peptonoids, I cannot say. There are several possible explanations. The growth of the germ may simply be more rapid in one than in the other, and the difference in the development may be only one of time; but a difference of this kind is sufficient for all practical purposes.

Then have the prepared milk foods no legitimate use? I think they have, and desire to point out what I consider to be their proper employment.

Even under the most favorable conditions milk can be kept unchanged only for a short time in summer. There is the same reason for the drying of milk and the preservation of its solids that there is for the curing of meat or the canning of fruit. The dried milk solids may be transported any distance and kept for any reasonable length of time, if properly prepared, without undergoing putrefactive changes. But they are to be used with children free from the summer diarrhœas rather than with those suffering from those complaints. Where the source of the milk supply is doubtful, a properly prepared milk food would be much more reliable than the raw milk. Besides, with any dilution or addition that may be made, cow's milk cannot be rendered identical with the milk of woman.

Can the milk of the cow be rendered more nearly identical with that of woman than it is by the simple dilution with water and the addition of milk sugar? All chemists, I think, agree that woman's milk contains more peptone than does the milk of the cow.

[1] THE MEDICAL NEWS, June 18, 1887.

Kirchner, who has given much attention to this subject, and has experimented largely, believes that the difference in the digestibility of milk from the cow and that from woman, is wholly due to the larger amount of peptone in the latter.[1] I cannot see, therefore, why the casein of the cow's milk should not be partially digested. That it should not be completely digested, I think there can be no question. It is certainly unscientific to feed any one for any length of time upon peptones altogether; especially is this true of children. To relieve the gastric juice altogether is to diminish its secretion. The muscle of the arm, the brain, and, indeed, every part of the body, is weakened by inactivity. The stomach can be no exception to this rule. It must have something to do, or it will soon be unable to do anything. There may be, and doubtlessly are, exceptional cases, in which the temporary administration of peptones exclusively is desirable. But these are exceptional cases, and the administration of the completely digested food should be only temporary. Certainly these cases do not include healthy children. For these reasons I generally prefer the partially digested meat preparations to the peptones.

If this be true, will it not be sufficient for the nurse to digest partially the cow's milk as it is fed to the child? There are these objections to giving advice of this kind. 1. If the source of the milk is doubtful, or if it has become contaminated by unclean vessels, or if putrefactive changes have already begun in it, the process of artificial digestion will not destroy the poisonous ferment. Indeed, the temperature at which the milk is kept during the artificial digestion will only favor the development of the poison. We have Dr. Holt's evidence that the use of peptonized milk is not to be recommended in summer diarrhœas.[2] 2. The artificial digestion, as carried out by the nurse, is not likely to be scientifically done. It will probably be neglected or amount to only a form, or it may be overdone and the taste of the milk spoiled, and too great a proportion of the casein converted into peptone. If partial artificial digestion is to be practised at all, and I see no reason why it should not be, it should be done under competent direction and when the milk is perfectly fresh.

Let us see what some of the most important properties of this prepared milk food should be. It should not contain any vegetable matter which is difficult of digestion.

This prepared milk food should be sufficiently nutritious in itself, and, consequently, should not require the addition of milk. In the use of all those prepared foods to which the addition of milk is necessary, the same danger of introducing the poisonous ferment into the alimentary canal exists as in the use of the raw milk. Many of the prepared foods contain such small amounts of proteids that the addition of milk becomes necessary. They should contain a larger per cent. of milk solids, obtained by the evaporation of milk in vacuo.

Attention should be given to the amount of inorganic salts, especially of lime and phosphoric acid, in a prepared food. A proper amount of these substances is as necessary to the health and growth of the child as are fats, proteids, and carbohydrates.

The carbohydrates present in such a food should not be in the form of grape sugar, but as milk sugar and dextrine. The grape-sugar is not supposed to have any specially injurious or poisonous properties; but it ferments too rapidly and for this reason is objectionable. By roasting wheat flour its starch is converted into dextrine, and this roasted flour mixed with milk solids, obtained by the evaporation of milk in vacuo, forms a food sufficiently nutritious, and one which may be kept indefinitely without putrefactive changes occurring in it.

Prof. J. Lewis Smith, in his excellent work on *Diseases of Infancy and Childhood*, speaks well of the roasted flour; and this, added to milk solids, makes the best infant food known to the writer.

BERGEON'S METHOD OF TREATING PHTHISIS.[1]

BY EDWARD T. BRUEN, M.D.,
ASSISTANT PROFESSOR OF PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA.

In the early part of February, 1887, I determined to try the plan of treatment of pulmonary consumption by injections of hydrogen sulphide in small quantities, propelled by currents of recently prepared carbon dioxide. This method of treatment was inaugurated by Dr. L. Bergeon, of Lyons, some four years ago, and it should be carefully borne in mind that the principle upon which Bergeon has based his treatment is that the disastrous results of pulmonary tuberculosis are hastened by the septicæmia set up by absorption of the products of suppuration from lesions in the bronchial passages, and in pulmonary and bronchiectatic cavities. Bergeon has suggested that repeated and prolonged bathings of the suppurating surfaces with a safe antiseptic agent controls the suppuration and gives the lesions an opportunity to undergo cicatrization, while in consequence numerous unpleasant and even dangerous symptoms are modified or controlled. Bergeon has not claimed that the number of bacilli of tuberculosis has been reduced in any considerable proportion of cases.

It may be assumed that there are three indications for the treatment of phthisis of prime importance.

The first is to secure some agent which will act upon the cause or causes of the disease. Since the essential etiology of phthisis is obscure, we resort to those measures which tend to overcome the well-understood predisposing causes, and increase the general health—climate, diet, and hygiene—alteratives and tonics have a well-recognized place in modifying these predisposing causes. Should the bacillus of tuberculosis be the real cause, we lack thus far a specific therapeutic remedy, and from my

[1] Read at the meeting of the Association of American Physicians, Washington, June 3, 1887.

records it does not appear that Bergeon's method will help us much with this indication for treatment.

Recognizing that pulmonary consumption is attended by general wasting of the tissues, the second indication is to prevent, by superfeeding, their further destruction; and, in general, it is true that in proportion as the vitality of the organism is increased, the number of bacterial organisms present in the sputa diminishes, especially the tubercle bacillus, because the healthy tissues are unfavorable culture media. I think the record of subjoined cases will show that sometimes Bergeon's treatment, by controlling or modifying certain prominent symptoms of phthisis, will enable us better to fulfil this part of the therapeutic management of phthisis.

The third indication is the medicinal management of special symptoms as they arise.

Bergeon's treatment would seem to be an important therapeutic measure. Whether it will prove sufficiently potential to win a permanent place in professional opinion, more time is required to determine. When I began to use the treatment it appeared to me probable that we should secure a modification or arrest of the suppurative process. If this was successfully achieved reduction in temperature, modification or suspension of night sweats, diminished cough, and expectoration would follow, and one might even hope in some cases to abolish bronchial catarrh. With the removal of these symptoms we might anticipate an increase of appetite, and, through the modification of the phthisical process, an increase of flesh.

In a preliminary report published in THE MEDICAL NEWS of April 2, 1887, the results of about two months' use of the method upon twenty-five cases seemed to justify the above anticipations. Most of the patients suffered from advanced lesions of pulmonary phthisis, nearly all were associated with cavities, marked bronchial catarrh, and several presented decided laryngeal disease. I reported one case of catarrhal or broncho-pneumonia, with implication of one lung in which entire convalescence ensued after treatment for eight weeks by Bergeon's method. In another instance the lesions were phthisis with pneumothorax, and the same marked benefit accrued after treatment.

Since April I have been able to follow continuously fourteen of the first cases. Out of the twenty-five cases two have died, in one I obtained a post-mortem which I will subsequently detail. Twelve cases remain in the same condition in which they were when I wrote my paper in April—that is to say, the physical signs remain unchanged; the temperature still above normal, the flesh and strength not increased after the first gain of, say, an average of five pounds. Yet the patients undeniably feel better: the process of suppuration with its attendant evils has been modified, suppressed, or controlled, and it must be admitted that the patients have been benefited by the treatment. Since April 2d I have applied the Bergeon method to twenty-four cases in private practice, and to thirteen additional hospital cases, so that in all I can present sixty-two cases in which the treatment has been applied in a systematic manner.

CASE I.—Mrs. T., æt. forty-five. Tubercular consolidation of the right apex. Duration of illness two years up to the date of the gas treatment, which was begun April 15, 1887. Temperature 99° A.M., 101° P.M., and so continued until April 24th, since which time it has continued at 99°. Pulse has averaged 100 throughout. Expectoration moderate in amount—about two ounces daily. Examination of sputa April 15th: rather numerous tubercle bacilli, and extremely numerous other rods and micrococci. April 23d: very numerous tubercle bacilli, extremely free from other bacteria. May 20th: same result. General condition of the patient much the same. Some increase in flesh. Sputa less in amount.

REMARKS.—Patient says she feels much better and the treatment seems to have been beneficial.

CASE II.—Brereton, æt. sixty-three. Implication of both lungs in patches. Tubercular disease with fibroid thickening; dry pleurisy on both sides of chest. Marked dry friction râles audible over axillary regions. In this case the beneficial results of treatment have been conspicuous. The patient has gained twelve pounds in flesh, appetite excellent. Temperature and pulse both average one hundred after seven weeks treatment. April 4th, moderate numbers of tubercle bacilli. No other bacteria.

April 23. Rather numerous tubercle bacilli in sputa, no other bacteria seen.

May 9. Moderate numbers of tubercle bacilli; large numbers of other bacteria.

REMARKS.—This case certainly improved decidedly. Patient had previously been confined to bed four months—at date he is ready to resume work—and the disease is latent. The result of treatment compares favorably with the most satisfactory cases of climatic treatment.

CASE III.—Sarah B., æt. twenty-eight. Ill five years. Expectorates about a teacup of matter daily. Mother died of phthisis. Diffused consolidation of left lung; apex cavity. Very numerous tubercle bacilli; no other bacteria seen.

April 14. Temp. 102°; pulse 100, P.M.

20th. Temp. 98.5°; pulse 96, P.M. Temp. 99°, A.M. Thereafter temperature did not rise above 99°, pulse 84, until May 20th.

May 20. Treatment discontinued.

REMARKS.—In this case the treatment has been beneficial—although there has been no change in physical signs, or character of the sputa.

CASE IV.—Geo. W., æt. twenty-eight. Cough two years standing. Incipient phthisis of right apex. Cough ringing and very annoying. Expectoration scanty. Weight one hundred and thirty-five at best, at present weighs one hundred and thirty. Microscopic examination of sputa.

April 15. Moderate numbers of tubercle bacilli with somewhat large numbers of other bacteria, some round epithelial scales not containing bacteria.

25th. Some tubercle bacilli, other bacteria not seen.

30th. Very numerous tubercle bacilli.

May 20. Rather numerous tubercle bacilli, no other bacteria.

In this case at date there are evidences of fresh cold—*i. e.*, bronchial catarrh over middle right pulmonary lobe. Physical signs at apex unchanged. General health better—but this improvement is doubtless attributable to careful dietetic management. Patient advised to go to San Antonio,

Texas, and continue gas treatment and examinations of sputa.

Case V.—Maitland, æt. twenty-six. Impaired resonance over right upper lobe. Prolonged harsh expiration, moist râles. Impaired mobility of right apex. Has been losing flesh and strength with cough for three months. Gas began March 26th in Philadelphia Hospital. Temp. at that date 101° F. April 1st the temp. was normal. Respiration 24, pulse 90. Thereafter until the date of discharge from the ward the temperature with one or two exceptions has continued at the normal point. Weight increased five pounds during treatment.

April 25. A few tubercle bacilli, very numerous other bacteria, and the same appearances persisted when he was discharged from the hospital, May 10th.

Remarks.—In this case, although the process is latent, yet undoubtedly great benefit accrued from the treatment.

Case VI.—Carl G., æt. thirty, German. Admitted to hospital March 25th. Physical signs the same as in Maitland. Temp. 100°. Weight one hundred and twenty-nine and a half pounds. Under treatment from March 25th until May 2d. With exception of April 4th, 5th, 6th, and 7th, on which days temperature rose to 102°, the temperature was normal, pulse 70–80, resp. 26–30. Weight increased from one hundred and twenty-nine and a half to one hundred and forty-four and a half pounds on May 2d, the day he was discharged.

No tubercle bacilli could be detected, although repeated examinations of the sputa were made.

Remarks.—In this case great benefit followed the treatment—yet the day patient was discharged temperature registered 100°, and it was evident that in this case also latent disease still existed.

Case VII.—Gallagher, æt. twenty-six. Philadelphia Hospital case. Tubercular inheritance. Cavity at right apex and implication of entire right lung. Case observed from February 6th until May 26th. Temperature ranged from 97° to 102° from February to March 2d. Gas commenced March 3d. Temp. on March 3d, ranged 98° to 100°, and continued the same for one week. The previously noted wide diurnal variations of temperature again commenced and have continued to date. Sputa examined and found to contain tubercle bacilli on each examination.

Remarks.—This patient gained six pounds while under the gas treatment. He also expresses himself as feeling well. Sputa small in amount, yet still contains bacilli, and the temperature record still continues unchanged. Fair result considering the lesions.

Case VIII.—James C., æt. twenty-three, admitted to hospital April 11, 1887. Ill two weeks previous. Physical sign of consolidation of the right upper lobe; apparently a case of acute catarrhal pneumonia. Treatment of general character from April 11th to May 12th, at which time the signs of consolidation persisting, the sputa was examined and found to contain numerous tubercle bacilli; no other bacteria. On second examination, May 28th, same result. But on the 12th of May the gas treatment was inaugurated, and within one week the temperature, which had previously ranged from 100° to 104°, became normal; pulse likewise, the sputa lessened. On May 31st patient has a normal temperature and pulse, does not expectorate, and indications for recovery seem favorable.

Case IX.—Sullivan, æt. forty-seven, entered Philadelphia Hospital February 2d. Ill two years. Consolidation of right apex; general bronchial catarrh with tendency to general pulmonary emphysema. Case noted from February 6th to May 22d.

April 8. Negative examination; no tubercle bacilli.

25th. Sputa contained few tubercle bacilli; no bacteria. May 6th very numerous tubercle bacilli; no other bacteria seen. Temperature record exhibited diurnal variation of temperature from 100° to 101°, from February 12th to 26th. No record kept from February 26th to March 9th, at which time the recorded temperature was 101°. Weight, one hundred and twenty-five pounds. Gas commenced. Temp. 97° to 98.2°, until March 21st, at which time weight was one hundred and thirty-two pounds. From March 26th until April 14th, temp. again 101° to 102°. From April 14th to May 2d, temp. 98° to 99.5°. No increase in weight. Pulse averaged 90 throughout; respiration 22.

Remarks.—In this patient the improvement has been very decided, the outbreaks of high temperature being due to exacerbations of bronchial catarrh. Treatment still continued.

Case X.—Eagen, æt. thirty-six. Ill two years. Large cavity at right apex; extensive consolidation in balance of lung. Confined to bed. Copious night-sweats. Copious expectoration. Very weak. Weight, one hundred and eleven pounds. Anorexia, coated tongue. Temp. 101°. Gas treatment March 2, 1887. From that time until April 24th, temperature rose above 99° on only two or three occasions. Weight, April 11th, one hundred and fifteen pounds. No night-sweats occurred after one week of gas treatment. Tongue clean, appetite good, and able to walk about. Sputa on April 8th and 19th, contained extremely few tubercle bacilli, many diplococci, a few rods.

Remarks.—In this case the improvement in general condition was marked, and, considering the extent of the pulmonary lesions, very satisfactory.

Case XI.—Gus G., æt. forty-seven. Fibroid phthisis. Copious expectoration. Had been in hospital six months previous to gas treatment. Daily hectic. Temperature constantly above 100° F. His case has been reported because from the time gas treatment was inaugurated, March 2d, until April 24th, temperature ranged between 96° and 98°, and pulse averaged 76. Expectoration markedly lessened. General strength much increased. Total gain in weight in time mentioned, five and a half pounds. Sputa contained in three examinations, numerous tubercle bacilli; no other bacteria.

Remarks.—In this case an improvement has been very positive, considering the gravity of the lesions.

Case XII.—Mrs. W., æt. thirty-five. Consolidation of left upper lobe. Small localized cavity in the left apex anteriorly. A few mucous râles audible. Balance of both lungs normal. Expectoration about a teacup full daily. Weight, one hundred and forty pounds.

April 1. Temperature 101 P.M., 99° A.M. Microscopic examination of sputa: moderate numbers of tubercle bacilli and long chains of streptococci with zooglœa of micrococci. During treatment the temperature in the morning was steadily lowered during the first week ending April 7th, averaging from 99° to 100°. During the period from April 8th to 24th, normal temperature was recorded. From April 24th to 30th it rose, the record showing a fluctuation from 99° to 101°. Pulse throughout averaged 100. No night-sweats during the treatment. Cough always troublesome, especially at night. No gain or loss of weight. No gain in ability to control nervous symptoms.

April 23. A few tubercle bacilli in the sputa.
May 1. Abundant tubercle bacilli.

REMARKS.—Treatment, although for a time seeming to control the temperature and reduce the sputa in amount, has terminated practically in a negative manner.

CASE XIII.—Mrs. K., æt. forty-five, married. Tubercular family history. Diffused consolidation of right lung. Ill two years. Weight, one hundred pounds. Annoying cough and profuse expectoration. Temperature April 1st, 99° to 102°. Gas treatment commenced. Temp. 98° A. M., 102° P. M., until May 2d. From May 2d to 10th it was 98° to 101°. From May 11th to 16th it was 98° to 99°. From May 16th to 24th it was 98° to 102°. Pulse has averaged 100. Expectoration throughout markedly lessened. Appetite improved Morale improved. Examination of sputa April 1st, very numerous tubercle bacilli; no other bacteria seen. April 25th, numerous tubercle bacilli and other bacteria; very numerous diplococci and diplo-bacteria; long streptococci; long filaments, and long rods. May 8th, very numerous tubercle bacilli and a few other bacteria.

REMARKS.—Entirely negative results in this case according to records of temperature and sputa, although patient feels better.

CASE XIV.—Mrs. F., æt. twenty-eight. Diffused consolidation of right lung, with cavities in upper lobe; abundant expectoration; night-sweats; temperature uninfluenced by treatment, registering constantly 101° A. M., 103° P. M. Pulse uninfluenced, ranging from 120 to 140. Treatment commenced March 24th, and continued until death of the patient, May 4th. Microscopical examination: sputa, numerous tubercle bacilli, large numbers of streptococci, a few tetragenous micrococci, a few large epithelial scales filled with bacteria. These appearances were practically unchanged throughout.

CASE XV.—Mr. H. Implication of upper lobes of both lungs. Lower lobes of both lungs normal. Abundant mucous râles at right apex, anteriorly and posteriorly; the same over left upper lobes, but not so numerous. Temperature 99°; several ounces of mucopurulent matter expectorated daily. Treatment inaugurated March 31, 1887. Examination of sputa revealed, April 8th, few tubercle bacilli. April 22d, rather numerous tubercle bacilli; no other bacteria seen.
May 14. Same appearances.

REMARKS.—In this case there was a notable gain in flesh, some seven pounds in all; general condition improved, viz., spirits and appetite. The treatment is still being continued, the patient claiming to feel improved. I believe that, in the absence of decided improvement in the physical signs, the result of treatment is doubtful.

CASE XVI.—Mr. R. Family history tubercular. Duration of disease, three years. Tubercular disease of both lungs, with fibroid thickening, especially of upper lobes; a great deal of vesicular emphysema; numerous fine, crackling râles over both lungs. Treatment commenced April 20th. Few tubercle bacilli; no other bacteria.
May 8. Moderate number of tubercle bacilli. Numerous other bacteria.

REMARKS.—Patient felt improved while taking treatment. Appetite better; cough and expectoration less; but there was no tangible evidence that treatment had been beneficial, when patient returned to his home to continue the treatment himself.

CASE XVII.—Mr. S., æt. twenty-four. Ill three years. Most of that time spent at Red Bluffs, Cal., and in Colorado. Family predisposition to phthisis. Dulness on percussion from clavicle to fourth rib, with impaired mobility; feeble bronchial breathing; abundant mucous râles and expectoration.
April 20. Sputa; very numerous bacilli; no other bacteria seen.
May 10. Sputa; same. Treatment discontinued at this date on account of negative effect.

CASE XVIII.—Mr. S., æt. twenty-eight, native of Boston. No predisposition to phthisis. Ill one year, which had been spent at Los Angelos, Cal., and vicinity. Physical examination of lungs revealed cavity in left apex and extensive disease of left lung, with implication of right apex; abundant muco-purulent sputa, containing numerous tubercle bacilli. Temperature 104°, pulse 130. This patient had from time to time been subject to diarrhœa, and the use of gas within three days brought on diarrhœa, which compelled relinquishment of the plan of treatment, although several trials were made.

CASE XIX.—Mr. P., æt. thirty, English. Ill one year. Implication of both lungs by tubercular thickening; marked tubercular laryngitis, with aphonia; profuse muco-purulent expectoration.
May 8. Enormous numbers of tubercle bacilli; no other bacteria seen, but contrast staining poor.
20th. Same appearances practically.
26th. No appreciable improvement. Treatment continued.

CASE XX.—Mr. M., æt. sixty-three. Emphysema and bronchitis; profuse expectoration. In this case, after a two weeks' course of treatment, marked relief of the bronchial catarrh.

CASE XXI.—Mr. K., æt. fifty-two. Ill six years; five years spent in travel in Europe, Colorado, and the South. Cavity in left apex, with consolidation of upper lobes of both lungs; abundant mucous râles.
April 26. Treatment commenced.
May 8. Rather numerous tubercle bacilli in slide; other bacteria in enormous numbers.
26th. Tubercle bacilli not numerous; no other bacteria.

REMARKS.—At date the physical signs remain as at commencement of the treatment, and although the patient is somewhat stronger, the results of treatment are as yet negative. Treatment is being continued.

CASE XXII.—Mr. W., of Shamokin, æt. forty-five. Ill one year. Implication of both apices; marked bronchial catarrh; loss of flesh; anorexia. Under treatment from August, 1886. Last winter spent in Thomasville. Temperature throughout illness has been about 100° F. Gas treatment commenced May 5.
May 9. A few tubercle bacilli; immense numbers of other bacteria, including numerous streptococci.
15th. Same result.
20th. Examination, extremely few tubercle bacilli; a few other bacteria.

REMARKS.—In this case the treatment so far has been entirely negative.

To recite additional cases would probably involve wearisome repetition. Among my private cases the following statement must suffice:

CASE XXIII.—Miss Katie J., æt. twenty-two. Bronchial catarrh, with incipient phthisis. In two weeks bronchial catarrh markedly benefited, but hers was one of the few cases in which the use of the gas seemed to have a depressing effect upon the general system, and

I have deemed it more prudent to withdraw this form of therapeusis. In only three cases have I noticed any such result.

CASE XXIV.—Mr. M. One year's illness. Implication of left lung throughout. Two weeks' treatment. Feels much better. Physical signs unchanged. Still under treatment.

CASE XXV.—Mr. B., Avondale. Tubercular disease of both apices. Negative result.

CASE XXVI.—Mrs. R. Tubercular disease of upper lobes of both lungs. Two weeks' treatment. Negative result. Treatment now in progress.

CASE XXVII.—Jensen, æt. twenty-five. Illness nine months. Implication of right upper lobes, with small cavity at right apex; fine moist rales throughout right lung. Negative results in two weeks' treatment, but the same measures have been continued.

The sputa has been carefully examined in all cases without in a single instance detecting any variation in the number of the bacilli. In order to have this portion of the clinical study as impartial as possible, Dr. E. O. Shakespeare has conducted the examination of the sputa without a knowledge of the clinical studies, using the Koch-Ehrlich rapid method, modified by Rindfleish. Dr. Shakespeare has stated his belief that the bacilli did not respond quite so decidedly to the stain, nor color so brilliantly as when stained for the first time before the gas was used. But we do not lay great stress upon this point.

In addition to the histories already reported in detail, a close study has been made of twenty-five additional cases of phthisis. The subjects represented instances of moderately advanced lesions with one or more pulmonary cavities. The cases have improved in flesh by a gain of several pounds, have had lessened cough and expectoration, increased appetite and spirits, but yet present practically unchanged physical signs, and still have a temperature of over 100° F.

The following additional cases, still in the Philadelphia Hospital, and representing the same lesions, have also received the gas, but with negative results:

CASE XXVIII.—N. F., April 5, 1887, began treatment, and it is still in progress.

CASE XXIX.—W. K., March 13, 1887, began treatment, discontinued May 22, 1887.

CASE XXX.—E., April 1, 1887, began treatment. Treatment now in progress.

CASE XXXI.—F., April 3, 1887, began treatment. Treatment now in progress.

CASE XXXII.—B., February 10, 1887, began treatment. Treatment discontinued May 18, 1887.

The following cases, of the same character as the foregoing, have been discharged from the Philadelphia hospital, so much relieved as to be able to return to their work—yet in whom the disease is certainly only latent.

CASE XXXIII.—J. W., February 10, 1887. Discharged April 10, 1887.

CASE XXXIV.—W. H., February 10, 1887. Discharged May 6, 1887.

CASE XXXV.—McN., gas, February 6, 1887. Discharged April 10, 1887.

CASE XXXVI.—McC., February 15, 1887. Discharged April 10, 1887.

The first date represents the inauguration of the gas treatment—and it was continued until the discharge of the patients.

CASE XXXVII.—The case of Jennie B., phthisis with pneumothorax, treated with the gas from February 28th to April 8th, with marked benefit, was reported in a previous article (THE MEDICAL NEWS of April 2d).

CASE XXXVIII.—As was also the case of Lizzie F. —under the title of broncho-pneumonia. In this case the treatment was continued from February 1st to April 7th, when the patient was discharged, apparently in good health and without any physical signs of pulmonary disease.

Two cases died while the treatment was being conducted—both cases of advanced phthisis. I report extracts from the post-mortem examination of one of them:

CASE XXXIX.—J. McM., æt. thirty-seven, admitted to hospital June 7, 1886. Died April 12, 1887. Marked pleural adhesions over apex of left lung—a large cavity was discovered in the upper lobe of this lung—cavity contained a thin grumous material. The inner surface of the walls of the cavity were moderately smooth and firm. The cavity was in communication with the bronchus. The lower lobe was covered by a moderately healthy pleura, and was studded by a few points of bronchopneumonia and an enormous number of firm translucent miliary tubercles. Along the upper and anterior edges of the upper lobe there were a series of small anfractuous cavities containing a little fetid purulent matter, but possessing rather smooth walls. The parenchyma of this lobe otherwise normal. The right visceral pleura of the upper lobe was adherent to the costal pleura. The upper lobe contained two anfractuous cavities about the size of a walnut, nearly empty and having rather smooth walls, and containing a large amount of purulent contents. The parenchyma of the other lobes of the right lung were abundantly studded with aggregations of miliary tubercle, which were separated by more or less healthy pulmonary tissue.

This case was treated with the gas from February 6th to date of death. His symptoms were ameliorated by the use of the gas, but no evidence of tendency to healing of the pulmonary lesions could be recognized—obstinate diarrhœa preceded death—the small intestine was found to be markedly hyperæmic throughout, with prominence of the papillæ. No enlargement of Peyer's patches. No pronounced ulceration throughout the whole extent of colon or rectum. In the large intestine the hyperæmia was less marked, but there were numerous, very minute, scarcely perceptible, round follicular ulcers.

To sum up the results of the examination of these cases, the record will be, benefited, forty-two cases, of these, Lizzie F., M., and G. seemed to be in good health—though dulness and feeble breathing can be still detected over the portion of the lung which had been implicated—of the three, Maitland was the only case in which tubercle bacilli were recognized in the sputa, and the pulmonary disease is probably latent. Among the fifteen cases reported in which the results were negative, were three cases in which the treatment seemed to have a decidedly good effect, but their condition has fluctuated so much that I have, for fairness' sake, placed them in the negative list.

The favorable effects secured by the treatment were lessened cough and expectoration, and disappearance of the physical signs of bronchial catarrh. Together with these results came lowered temperature and suspension of night sweats. Temporarily reduction of the pulse-rate fifteen to twenty beats,

and temperature lowered from half a degree to one degree during administration of the gas.

In most of the cases I used the artificially prepared sulphur water, viz.: five grains of sulphide and five grains chloride of sodium to a pint and a half of water, and this seems to have been the most satisfactory solution. After employing the treatment for several weeks, in some cases I have increased the proportions of the two salts gradually, adding seven and a half, ten, fifteen, and twenty grains by weekly additions; but in cases in which I have failed to secure good effects from the weaker solutions, I have derived no benefit from increasing the strength of the solution. Recently I have used the Sharon Spring sulphur water, and added the sulphide and chloride of sodium each day. By keeping the bottle tightly corked, I have been able to use the same bottle of water on two consecutive days.

There are a few details of consequence in administering the gas. Until tolerance is established, a small amount, one pint to a quart of gas, has been used daily, then the same amount twice daily, and gradually increased. From a gallon to a gallon and a half can be ultimately injected without discomfort. If there is pain after using the gas, it should be used but once daily, and only a small amount at a time; the strength of the solution of sulphuretted hydrogen should also be reduced; for instance, two and a half grains of sulphide and chloride of sodium may be used. It is desirable to inject slowly, consuming an hour in giving a gallon of gas, and the patient should rest quietly an additional half hour until the gas is entirely absorbed from the bowel. The longer time taken to administer the gas the better, especially when any pain is caused by the treatment. The admission of atmospheric air into the bowel should be sedulously avoided.

In cases of intestinal lesion or diarrhœa, my experience has been unfavorable to the use of the gas, except in very small quantities. Chronic peritonitis also forms a contraindication to its use. In about two cases out of ten I have noted a faint reaction indicating sulphuret of lead, which was obtained by holding filter paper, saturated with acetate of lead, to the mouth of the patient during the administration of the gas. The reaction was in no case decided, and I cannot account for its absence in so many instances.

In none of the cases have any injurious effects been observed, but I have noted in some individuals subnormal temperature during the use of the gas, and also when the stronger solutions of sulphide of sodium were used the appetite and strength of the patients seemed impaired and their spirits depressed.

Two suggestions may be given for the failure of the treatment to accomplish better results. The first of these applies only to hospital cases. It is impossible in a large general hospital to secure the detailed attention to diet necessary to suit the capricious appetite of the consumptive. In treating consumption it is absolutely necessary to increase the vitality of the tissues, so that they will be unfavorable culture media for the bacilli.

The second suggestion is, that in cases with inherited tendencies to phthisis, or in those who acquire a phthisical tendency, there is great vulnerability of the mucous membranes, which ever fosters an outbreak of catarrhal processes in the bronchial structures. In this way the good effects of the treatment are constantly opposed. I incline to think that suitable climatic environment is an all important adjunct to the proper settlement of the value of Bergeon's treatment. But it is certainly an important addition to our therapeutic equipment to have an agent capable of influencing very markedly bronchial catarrh in so many cases, especially the stay-at-homes.

In a word, Bergeon's method, so far as I have used it, is chiefly valuable in those cases of pulmonary disease attended with bronchial catarrh. But I fear the trouble and detail necessary to its successful use will prevent many from employing the method, and I can easily see that the limitation of the power of Bergeon's method will cause it often to be set aside for other plans of treatment.

In conclusion, I believe our efforts in the therapeusis of phthisis should always be directed rather to those measures which tend to establish the general health, rather than to hunt up specific forms of treatment. Suitable climatic conditions, and judicious alimentation, and appropriate personal hygiene remain, in my opinion, the first principles in the therapeutic management of phthisis, and Bergeon's treatment should be considered an adjunct to these.

SIX CASES OF PHTHISIS AND ONE OF CHRONIC BRONCHITIS WITH EMPHYSEMA AND ASTHMA, TREATED BY RECTAL GASEOUS ENEMATA.[1]

By FREDERICK C. SHATTUCK, M.D.,
VISITING PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL AND THE HOUSE OF THE GOOD SAMARITAN, ETC.,
AND
HENRY JACKSON, M.D.,
DISTRICT PHYSICIAN TO THE BOSTON DISPENSARY.

THE sudden and widespread attention which Bergeon's method of treatment of phthisis has received is somewhat remarkable, especially considering the demands which the method makes upon the time of the physician and his assistants. The chief reasons for this interest lie in the great frequency of the disease, the unsatisfactory results of treatment in a large proportion of cases, the professional standing of Dr. Bergeon, who practised his method for two years before giving it wide publicity, and the rather enthusiastic notice of it by Dr. Henry Bennet in the *British Medical Journal* of Dec. 18, 1886. In this country professional utterances have thus far been cautious. The daily press has, however, shown its characteristic enterprise in bringing the new method into notice.

As soon as Bennet's article appeared I resolved to try the treatment, having suitable cases at command. An apparatus was made and about the middle of January we began to apply the treatment. The chief difficulty which we encountered at the outset was in securing a natural sulphur water.

[1] Read at the meeting of the Association of American Physicians, Washington, June 3, 1887.

Chamberlain has used sulphide of calcium as a source of the H_2S gas and without ill effects: the inflammable character of this substance and its destructive action on rubber decided us against its use. Bergeon states that an artificial H_2S water does not act as well as a natural one. But it is very hard to understand in what respect sulphuretted hydrogen evolved by the passage of carbonic acid gas through a solution of sulphide of soda, differs from sulphuretted hydrogen made from sulphide of iron and sulphuric acid. A definite chemical combination must be always the same. Reasoning thus, we made our sulphuretted hydrogen and passed a full stream of it through water in pint beer bottles. At first the gas was allowed to flow through each bottle for about five, subsequently for two to three minutes, as experience made us think that our patient was getting too much of the gas. Whether this reduction in time really resulted in any reduction of the strength of the solution is very problematical. Water at the ordinary temperature and pressure of the atmosphere will dissolve about three times its own volume of H_2S gas. We feel safe in assuming that our solution contained a double volume of the gas. A half litre of solution thus contained one litre[1] of gas. The source of sulphuretted hydrogen which is recommended by Bergeon is the water of Eaux Bonnes, through a half litre of which carbonic acid is passed, setting free the sulphuretted hydrogen from its combination with soda. The amount of H_2S gas which can be developed from the sulphide of soda contained in one half litre of Eaux Bonnes water is about 3 c.c. Morel, Bergeon's pupil, says that the same bottle of water can sometimes be used a second time, all the H_2S gas not being utilized at one injection. But let us grant that the gas capable of development from one half litre is exhausted in one administration, and that all the 3 c.c is passed into the intestine, thence absorbed into the veins and exhaled from the lungs. It is somewhat difficult for one who is not a believer in infinitesimal doses to feel convinced that so very small a quantity can exert a marked effect of any kind. The solutions which have been used in the Hopital Cochin in Paris contain, according to Prof. H. C. Wood,[2] about 150 c.c. H_2S to the dose, and are consequently fifty times as strong as the Eaux Bonnes water.

The treatment is a product of Koch's discovery of the bacillus tuberculosis, and was based on the idea of bringing a substance hostile to their life, but not injurious to their host, into intimate contact with the animals. Bergeon finds that the sputum in tubercular cases still contains bacilli, even when it is reduced to mere mucus, a fact which seems to show clearly enough that the gas is not fatal to this form of organism. The good effects which he sees follow the treatment he now attributes to the antiseptic (?) virtues of the gas and its curative effect on local lesions. Sulphuretted hydrogen is certainly not inimical to the bacteria of putrefaction. Trudeau has treated cultures of Staphylococcus aureus and of the bacterium of blue pus with Richfield Spring and Eaux Bonnes water, and finds that the organisms are none the worse for the gas. He also treated a pure culture of the bacilli of tuberculosis in the same way with similar results. On the other hand Niepce found that tubercular sputum exposed for ten minutes to an atmosphere containing three per cent. of H_2S was entirely innocuous to rabbits, while the same sputum first exposed to the gas produced the disease in every animal inoculated with it.

It may be that the gas is a source of actual pleasure to the germs, and yet that it renders inert in some way the poisonous products of their activity—ptomaines and leucomaines. But here our knowledge is so slight that all is little more than speculation. The carbonic acid is thought to be therapeutically inert, except in so far as it obviates danger of irritation from the sulphuretted hydrogen. (Morel).

If H_2S gas passing through the lungs after introduction through the general venous circulation, exerts any preventive or curative influence on disease of those organs, New England, where probably more beans are consumed than in any other equal area of the earth's surface, ought to enjoy a remarkable immunity from tuberculosis and other affections of the respiratory tract. I do not need to tell you that such is not the fact.

The cases which were selected for the treatment were most of them far advanced. In acting thus we thought we were putting the method to a fairer, if severer, test. Great improvement in comparatively early cases, both in and out of hospital, under a general common sense treatment with full diet, is so common that one cannot but feel very sceptical as to the real value of any special treatment which may be superadded. A moderate improvement after special treatment in cases which were not doing well under general treatment is, it seems to us, more conclusive as to the merits of the former. Even here there is, however, a source of error which must be kept in mind. A new method of treatment is not infrequently followed by decided, though temporary, improvement in cases which are really incurable, though the influence thus brought to bear on the gray matter of the cerebral cortex. This sort of influence is as old as man himself, though since it has received the name of the "mind cure" the laity seem to think it an invention of the last year or two.

CASE I.—A delicate, nervous girl of eighteen, with advanced disease of the lower left lung, losing ground but free from fever. Bacilli in sputum.

Jan. 20, 1887. Two enemata, each of about one litre. She complained during the injection of some abdominal discomfort, but had no sharp pain.

21st. An enema of one litre in A.M. During the injection she complained of abdominal discomfort, was very pale and somewhat cyanosed. The pallor seemed to increase during the injection. All through the day she had abdominal pain, and was much prostrated. On account of the remonstrances of the patient and the apparently unfavorable effect of the injection, the treatment was omitted. A month later she was discharged at her own request, and we have heard that she has died since then.

[1] A litre is about a quart

[2] Therapeutic Gazette, April 15, 1887.

CASE II.—A woman of forty, with advanced disease; profuse expectoration containing bacilli; prostration; in constant fever.

Jan. 19. Two enemata, each about one and a half litre. No discomfort ensued.

20th. Two enemata, each about one and a half litre. In P. M., after second enema, a loose involuntary dejection with much flatus.

21st. At morning visit seemed very weak; lay on her back and was unwilling to move. Temp. 97.5°; pulse 120, very small and compressible; no enema was given.

24th. Strength and general condition improved over that of the last few days. The cough is much less frequent and the expectoration is diminished one-half. One enema of one litre.

25th. Two enemata, each one and a half litre, followed by no immediate discomfort.

26th. Weakness again very marked; a loose dejection during night. Treatment omitted.

Feb. 1. Sitting up and feels better. When it was suggested that the treatment be resumed, she remonstrated on the ground that it made her feel very badly, and no more enemata were given. She had six in all. A month later she died, gradually failing at about the same rate as before the special treatment was begun.

CASE III.—A girl of eighteen, in fair general condition, with limited consolidation at the right apex; scanty expectoration containing numerous bacilli. Not confined to bed and free from pain. Entered the hospital January 22, 1887.

Jan. 25. One enema of one litre without pain or discomfort.

26th. Two enemata, each one and a half litre. A little abdominal pain followed the injection.

27th. An enema of one and a half litre in A. M. Abdominal pain and vomiting continued through the day and the treatment was not resumed until

Feb. 11. Some loss of weight having been incurred during the interval and the physical signs having increased in extent. One enema of one litre.

12th, 13th, and 14th. Each A. M. an enema of one and a half litre without any unfavorable symptoms.

15th. One and a half litre in A. M., followed by nausea and vomiting, which continued during the day.

16th. Vomiting continues; no abdominal pain or discomfort; severe frontal headache.

The treatment was not resumed. The appetite and digestive power soon returned and were maintained. There was improvement in flesh and strength, though the physical signs showed that the disease was advancing. The whole number of enemata given was nine.

CASE IV.—A woman of forty, with slight signs at both apices; very marked rational signs; very harassing cough with moderate expectoration, which contained bacilli. Confined to bed.

Jan. 22 and 23. One enema of one litre each day, followed by no bad symptoms.

24th. One enema of one and a half litre. Slight abdominal discomfort toward the end of the injection.

25th, 26th, and 27th. Each day one enema of one and a half litre. Complained of discomfort after each enema, sometimes lasting for several hours.

28th. Diarrhœa and vomiting last night; is very weak and the cough is very severe. No enema.

Feb. 1. Vomiting has continued for the past three days and diarrhœa returned last night. The treatment was not resumed.

20th. She was discharged at her own request and died not long after. She had six enemata in all. While she was in the hospital her husband died; his loss and the helpless condition of her children, caused an intense depression of spirits which rendered any treatment quite hopeless.

CASE V.—A woman of forty, with chronic and advanced disease and cavity formation; moderate expectoration, nummular in character. Confined to bed.

Feb. 1. Enema of one litre without bad symptoms.

2d. Enema of one litre followed by slight abdominal pain.

3d. Enema of one and a half litre; expectoration rather less abundant.

4th and 5th. Each day one enema of one and a half litre. Says she feels better.

6th. Last night free hæmoptysis. The treatment was omitted and not again resumed. The hemorrhage recurred at short intervals until March 1st.

March 14. She was discharged at her own request, wishing to die among her friends. I have since heard that this wish had been fulfilled. She had five enemata in all. The effect was favorable rather than otherwise, and it is not likely that the treatment had anything to do with bringing on the hemorrhage.

CASE VI.—A woman of twenty-five, advanced in phthisis, with a large cavity at the right apex; abundant purulent expectoration containing bacilli. Is able to sit up most of the day. Much of the time has high fever and is then comfortable; if the temperature falls to the normal, she complains of feeling cold with general discomfort.

Feb. 15. An enema of one litre.

16th. An enema of one and a half litre. No discomfort.

An enema was given once a day until the 21st, the expectoration diminishing in quantity.

22d. Two enemata, each two litres, were given and repeated daily.

During the night of March 1st she was kept awake by abdominal pain.

March 3. She had severe left hemicrania with flushed face and hot skin. No enema.

4th. No enema; has lost upward of a pound in weight since treatment was begun.

5th. Two enemata of two litres each.

6th. Nausea, occasional vomiting; no enema.

7th. Nausea, weakness, feels flushed, pulse small and rapid.

8th. Feels better; one enema of two litres.

9th. One enema of two litres.

10th. Two enemata of two litres each.

11th. One enema. Headache and nausea in P. M.

12th. Headache and vomiting. Treatment was discontinued.

22d. No material change in the condition of the patient since February 1st.

Since the enemata were omitted headache and nausea have been absent.

During four weeks the patient had thirty-one enemata.

CASE VII.—A woman of thirty-five, in good general condition, for a long time subject to bronchitis, with occasional asthmatic attacks. The expectoration is often streaked with blood, and during the last seven years she has raised clear blood a number of times. Several of these attacks of hæmoptysis while under our observation in the hospital. The physical signs indicated only widespread bronchitis and moderate emphysema. The sputum was repeatedly examined for bacilli, with negative result.

Feb. 7. Enema of one and a half litres.

8th–9th. One enema daily without discomfort. Patient thinks she is better, and coughs less.

8th. Two enemata, of one and a half litres each.

9th. Two enemata, of two litres each. Sleeps better, and reports that "spit comes easier, and she can breathe deeper."

14th. After her second enema she complained for the first time of some abdominal pain.

17th. Cough is loose and infrequent; expectoration is less abundant, still streaked with blood.

27th. One or two injections were given daily up to this date, when she vomited, feeling chilly in the night. An enema was given, and shortly after the catamenia appeared. The treatment was omitted, and was not resumed. She had thirty-four enemata in twenty-three days.

March 23. Her general condition is much improved; the cough is infrequent, the sputum scanty. An occasional râle can be heard on the left lower back, and there are signs of slight emphysema.

During the gas treatment the patient had iodide of potassium, and linseed oil with simple syrup.

It would be easy to attribute a large share of the marked improvement in this case to the special treatment, were it not for the fact that a few months before the patient had gone through a similar, though rather less severe attack of bronchitis, with asthmatic seizures, in the hospital, and had made a recovery quite as rapid and satisfactory under ordinary medication through the stomach.

Summary of cases:

I. Number of enemata, three. They were followed by slight abdominal discomfort and decided depression of the general strength.

II. Number of enemata, six. They were followed by marked depression and, at one time, a condition nearly approaching collapse, with diarrhœa.

III. Number of enemata, nine. They were followed by slight abdominal discomfort, nausea, vomiting, and general depression.

IV. Number of enemata, six. They were followed by abdominal discomfort, nausea, vomiting, and diarrhœa; secondary to the vomiting, partial collapse.

V. Number of enemata, five. Though the patient was very weak, no local or general ill effect was noted; the patient thought she felt better. Treatment omitted on account of hæmoptysis.

VI. Thirty-one enemata in four weeks. No abdominal or general discomfort. No good effect except a diminution in the expectoration. Treatment finally omitted on account of nausea and headache.

VII. Thirty-four enemata in twenty-three days. No untoward symptoms. Gradual improvement under, and possibly through the gas treatment. (Emphysema and bronchitis.)

Before we attempt to draw any conclusions from the above cases, a few preliminary statements are in order. Bergeon's method was followed carefully, save in respect to the use of an artificial and much richer sulphuretted hydrogen water. It was found that the immediate discomfort was much less if the H_2S water was made quite hot before the CO_2 was pumped through. No odor of gas could be detected in the breath, nor was paper moistened with a solution of acetate of lead blackened when held before the mouth. No irritation of the rectum was noted in any case. The enemata were given two hours after breakfast and dinner.

We are not the only observers whose results have not been inspiring. De la Roche[1] reports three cases, two of phthisis, one of bronchial asthma. One of the tubercular cases improved in all respects; the second did well also, but on the twentieth day of the treatment severe colic came on, which ceased as soon as the treatment was stopped. On the resumption of the injections the colic returned, and a diarrhœa carried off the patient in a few days. In the asthmatic case the treatment had "effets désastreux," on the third day after the treatment was begun the patient had a paroxysm of unusual severity, from which it took her a fortnight to recover under a more customary treatment.

Osler[1] reports that a patient at the University Hospital in Philadelphia, nearly expired after one administration of the gas. Dana[2] speaks of nausea as resulting from it in some cases.

The number of our cases is small, but we think ourselves justified in drawing the following conclusions:

1. Toxic symptoms may follow the injection of sulphuretted hydrogen gas into the rectum, among such symptoms being nausea, vomiting, general depression or collapse, diarrhœa, and headache.

2. Strong artificial solutions of sulphuretted hydrogen mixed with carbonic acid, and injected into the rectum, are apt to cause abdominal discomfort; the risk of this is diminished by warming the solution of the former gas.

3. This method is in no sense a specific for phthisis. If useful, it is only as auxiliary to older and generally accepted methods.

4. The only benefit which we saw in our cases that can fairly be attributed to the enemata, was diminution in the amount of the expectoration.

To these conclusions we should like to add two impressions:

1. Recorded experience seems to show that there is considerable difference in different individuals—and perhaps in the same individual at different times—in the amount of sulphuretted hydrogen which can be safely injected into the rectum. *A priori* reasoning makes it almost incredible that the amount of the gas which can be passed through the lungs when Bergeon's method is strictly followed, is large enough to have any therapeutic value.

2. The good effects which have unquestionably followed the treatment on this side of the water, as well as in France, are, perhaps, largely attributable to the stimulus afforded by a novel method of treatment, which is of such a nature that the patient cannot but feel that not only something, but much is being done for him.

THE TREATMENT OF PHTHISIS BY GASEOUS ENEMATA.[3]

BY W. PEPPER, M.D., AND J. P. CROZER GRIFFITH, M.D., OF PHILADELPHIA.

INDUCED by the importance of the subject, and by the discouraging results of the various methods of dealing with phthisis, we commenced some experiments with Bergeon's treatment with gaseous enemata be-

[1] THE MEDICAL NEWS, 1887, I, No. 13.

[2] N. Y. Medical Record, May 7, 1887.

[3] Read by Dr. Pepper at the meeting of the Association of American Physicians, Washington, June 3, 1 87.

fore reports of investigations by American physicians had appeared in the medical press. Our work has proceeded steadily but slowly, and this report is even yet chiefly of a preliminary nature, since many of the cases are still under observation.

Following the papers which have just been read, and all that has been previously written on the subject, it will not be necessary to speak of the theoretical grounds on which this treatment was first advocated by its proposer, or to dwell upon its details.

Method.—In private cases we have used the Morel apparatus, substituting a solution of sodium sulphide —ten grains in one and a half pints of water—for the natural sulphur mineral water. In hospital practice we have sometimes pursued the same plan; sometimes proceeded in the following manner. The carbonic dioxide was procured already compressed in the large iron receivers in use for soda fountains. It was passed from these through the solution of sulphuretted hydrogen into a five gallon gum bag, from which the patients then received the injections. Thus in one case the bag contained pure carbonic dioxide, and in the other the gas already medicated. It could not be discovered that it made any difference which method was followed.

The injections were given from one to three times daily; and from two to six or more quarts of gas were employed. The administration of the injection lasted from fifteen minutes to one-half hour or longer, except in those cases in which the tolerance of the bowel was very quickly exhausted, and but little gas could be taken.

It is to be regreted that the observations made are not in every case so complete as could be desired. This was often unavoidable; in some cases because patients were treated in homes where no accurate record of temperature and weight could be obtained; in others, in hospital practice, because patients sometimes left before a final examination of the lungs could be made, and the presence or absence of improvement of physical signs noted.

The total number of patients upon whom the treatment was tried equals 34. 10 of these cannot be regarded as test cases in any sense, since the injections were given during too short a time to allow of any conclusions being formed. In one of these there seemed to be inability to retain the gas in the bowel; in another ill defined but unpleasant subjective sensations were produced, and the patient begged to have the treatment discontinued; a third patient died a few days after the enemata were begun; a fourth has but just commenced to receive the injections; in three cases colic was so intolerable that the treatment could not be persisted in, and three dispensary patients ceased their visits after two or three days.

Deducting then these 10, there remain 24 test cases to whom the enemata were administered for from 12 to 56 days; the average being 25.

Other treatment was frequently combined with that of Bergeon. Had the results been favorable, this fact might be urged against the justice of our conclusions. As the sequel shows, it can have no influence, except to militate against occasional possession of beneficial action by the gaseous enemata.

Probably the most convenient method of estimating results is to study the symptoms individually, and to notice the effects produced on them by treatment.

Fever.—The greatest improvement was noticed in the reduction of fever. The total number of cases in which a daily record of temperature was kept equals 16. Of these there were 4 whose temperature was more or less reduced during the administration of the gas. In 11 there was no appreciable effect; and in 1 the fever actually seemed to increase. In another instance (one of the 10 excluded from the test cases) it rose quite decidedly during the four or five days in which the treatment was given; though this was probably only a coincidence. In no case was the temperature brought from a persistently febrile to a continuously normal condition.

Weight.—In 20 cases in which the weight was recorded at frequent intervals, there were 8 in which the gaseous treatment was attended by more or less gain; the greatest increase being eight pounds in thirty-seven days. It is worthy of note that in this case there seemed to be no improvement in health. In 6 patients the weight remained stationary, and in 6 it was diminished, with or without a change in the severity of other symptoms. The increase in weight took place chiefly in hospital cases, and we cannot but believe that it was due very largely to complete rest and good food.

Cough.—Improvement in this respect was not even so marked as in the preceding symptom. In 7 of the 24 cases there was said to be more or less diminution of cough. In 2 of these this was undoubtedly true, as testified to by the attendants and friends. In the others the well-known hopeful disposition of phthisical patients laid the truth of their statements open to suspicion. Moreover, in 1 of the 8 the removal of a large amount of fluid from the pleural cavity was probably the chief agent in producing decrease of cough, if any existed; and another patient was taking a cough mixture as well as the gaseous treatment. In 3 cases the cough seemed actually to grow worse;—this being probably *post hoc* merely.

Expectoration.—As regards the diminution of the amount of expectoration, we were able to come to more definite conclusions, since the question did not depend to such extent on the statements of the patients. Out of 24 cases the quantity was somewhat decreased in 4 instances. In 5 patients it became more abundant, and in one of these, to whom the gas had been given fifty days, the increase was very marked. In the remaining 15 no effect could be perceived.

Bacilli.—The sputum of 30 patients was searched for tubercle bacilli, and the microbes found in 27 instances. A second examination was made at the close of the treatment in only 11 cases, and in but 4 of these was there even an apparent diminution in the number. It is extremely doubtful whether there existed here any real decrease in the absolute quantity of bacilli in the sputum.

Dyspnœa was recorded in comparatively few cases, and in only 3 of these did the patients claim that they had experienced any improvement.

Night-sweats.—Here, too, the cases reported are not numerous, as many of the patients did not suffer from them. In 1 case they were checked, and in 7 unimproved.

Physical examination.—The result of the physical investigation of the lungs of each patient was noted at the beginning of the gaseous treatment: and a final examination was made at the close of the treatment in every instance possible. As already explained, the latter could not always be accomplished. Nevertheless, a final study of the lungs was made in a considerable number of cases, and in *not a single case* was any improvement found. Even the patient who of all the 24 had made the greatest—and really very remarkable—progress, exhibited quite as many rales as fifty-six days before, when the treatment was commenced.

General condition, etc.—As regards the general condition of the 24 test cases under observation, there were but 4 in which any improvement could be noticed (2 decided, 2 slight), apart from the amelioration of the symptoms already mentioned. 7 patients grew worse, and 1 died. No observations were made on the temporary effect of the gas on *pulse* and *respiration*. The *appetite* was sometimes increased but usually not much affected. The enemata had a decidedly *hypnotic* influence in 3 cases.

Unpleasant effects.—As regards unpleasant symptoms produced by the treatment, one patient complained of feeling faint after the first injection; another had headache, and another suffered frequently from dizziness. The last patient had been given on one occasion, before we had commenced our observations upon him, about one quart of a mixture of equal parts of carbonic dioxide and hydrogen bisulphide, and promptly developed the most alarming symptoms. The pulse almost disappeared and the respirations became shallow; the patient was covered with cold perspiration, and completely lost consciousness. This condition lasted about three minutes, and the physician with him was obliged to use most energetic stimulation before the patient was out of danger. This incident proves the power and possible danger of sulphuretted hydrogen; but is not, of course, a contra-indication to the proper administration of the gas.

The tendency to nausea if the injection was given too soon after a meal, and the inclination to evacuate the bowels were also noticed in some of our cases.

But the only unpleasant symptom of any real moment was *colic*. This was complained of as often severe in at least 11 of the 24 cases: and, as already stated, 3 others suffered from it to such an extent that the treatment could not be employed. One individual was so severely attacked that he rolled upon the floor in pain. Colic was slight in a few cases, and not complained of at all in many. As other investigators had not written of much annoyance by it, we were led to suspect something faulty in our method of administration, but the most careful investigation has failed to reveal anything amiss.

While true that too large a quantity of gas gave pain, yet the colic was very often not controlled by giving smaller amounts. In some instances, too, equal volumes of gas at one time produced intense suffering, and at other times were well borne. Nor did a slow administration of the injection appear to prevent the cramp. The presence of air was carefully excluded; and, fearing that the iron reservoirs might possibly contain it, we discarded them for a time, but with no modification of the result. Moreover, colic was as often suffered by the private patients as by those in the hospital where the compressed gas was usually employed. Frequently the bowel seemed to grow more tolerant as time passed, while in other patients the reverse was the case.

A few of our cases serve as excellent warnings against the drawing of hasty and unwarranted inferences. In one of these the patient had abundant expectoration, troublesome cough, and signs of pulmonary consolidation, combined with a large element of chronic bronchitis and emphysema, besides being annoyed greatly by dyspepsia. The enemata were tried for a few days, but abandoned on account of the severe colic. He was then put upon a simple stomachic mixture, combined with good food and rest. He left the hospital after about two months, with the amount of expectoration very much reduced, having gained eight pounds, and saying he had not felt so well for a long time. Had he been able to take the gaseous enemata we would have undoubtedly attributed the good effect to them.

Another patient made the greater part of a surprising improvement in general health two weeks before the injections were commenced. Had Bergeon's treatment been instituted two weeks earlier, it would have gained unmerited credit.

To summarize in a few words our observations: Febrile temperature was sometimes lowered, but never to any great extent. Cough and expectoration were occasionally lessened, but oftener unaffected, and sometimes even increased. Weight was oftener lost or stationary, but a decided gain was frequently made; due, perhaps, partly to the gas, and no doubt, in part, to the improved conditions of life. Dyspnœa and night-sweats were rarely benefited; the physical signs were in no case altered: the general health was but seldom made better, and severe colic was a frequent and annoying symptom.

Our conclusions—so far as they can be formulated in a preliminary report of comparatively few cases—are: That the treatment of phthisis by gaseous enemata has had very undue value attributed to it; that it is seldom of any real benefit, but that it may prove serviceable in occasional cases.

Thanks are due Dr. D. T. Lainé, resident physician to the University Hospital, for his coöperation in the study of many cases; and to Dr. William E. Hughes for the notes of a number of patients treated by him in the Dispensary of the hospital. Prof. William Osler has also courteously placed at our disposal several cases of phthisis in his wards.

MEDICAL PROGRESS.

SUCCESSFUL REMOVAL OF A TUMOR FROM THE SPINAL CANAL.—On June 9th, MR. VICTOR HORSLEY removed a tumor from the spinal canal of a gentleman aged forty. The diagnosis of compression of the spinal

cord by a morbid growth was made by Dr. Gowers, who saw the patient with Dr. Percy Kidd. The patient was suffering from paraplegia, which commenced gradually six months ago, and from pain round the chest of four years' duration. Sir William Jenner afterward saw the patient, and confirmed the diagnosis. Dr. Gowers suggested that an attempt should be made to remove the growth. From the history of severe neuralgic pain in the back and along the course of the left sixth dorsal nerve which preceded the paraplegia, it was considered probable that the growth commenced in the posterior root of the nerve, and afterward produced pressure on the cord. The operation was performed by a long incision in the mid-line of the back, having its centre about the fifth dorsal, down to the spines of the vertebræ. The muscles were cleared off from the laminæ and retracted. The spines were removed by bone forceps, and then the laminæ trephined. An incision was made through the membranes and the cord examined, a tumor about the size of the tip of the little finger being eventually found on the posterior root of the nerve about the level of the third dorsal vertebra. This had pressed the cord forward and to the right, producing a deep depression in its substance. It was removed with the nerve to which it was attached. The incision through the membranes, which was at least three inches long, was not sutured; the wound in the soft parts was closed with sutures and drained. Strict antiseptic precautions were taken at the operation. Since the operation there has been no rise of temperature, and the pain has diminished. The painful spasmodic action of the muscles of the lower extremities from which the patient suffered has diminished, and there has been less rigidity of the legs, but the paraplegia continues. The growth, which was of a pinkish color, elastic and vascular, has not yet been submitted to microscopical investigation.—*Lancet*, June 18, 1887.

BERGEON'S TREATMENT AT VENTNOR.—DR. SINCLAIR COGHILL reports his experience with this treatment at the Isle of Wight as follows: My experience, so far, of Dr. Bergeon's treatment of consumption and other lung affections, both in private and hospital practice, has been altogether most encouraging—indeed, in some instances, surprising. I believe it is the greatest advance by far that has ever been made in the therapeutics of pulmonary diseases.—*British Medical Journal*, May 21, 1887.

DEDUCTIONS OF THERAPEUTIC VALUE FROM THE CLINICAL STUDY OF THE REACTION OF THE GASTRIC JUICE.—LANDOIS, in the *Revue de Médecine* of May 10, 1887, draws the following conclusions from an extended study of the gastric juice:

Hydrochloric acid when given for deficiency of gastric juice, should be given in large doses, forty to fifty drops; the quantity of pepsine given is not so essential.

The patient should take the acid in small doses of eight or ten drops every fifteen minutes until the entire dose has been taken: thus taken after meals abnormal fermentation is greatly lessened.

The treatment of hyper-acidity is most successful when alkaline waters are employed (Vichy, Carlsbad, etc.). Care should be taken that their usage be not too prolonged.

In simple gastric ulcer the neutral or alkaline reaction of the contents of the stomach is not necessary to a cure; the excess of acid only need be neutralized. Hydrocarbons must be largely removed from the diet and nitrogenous food substituted.

Lavage aids by removing abnormal acids and furthering the digestion of starches.

AGARICIN AS USED IN BELLEVUE HOSPITAL.—Agaricin (the active principle of agaricus albus) gives uniform results in checking excessive perspiration in phthisical and fever patients. The following formula is used at Bellevue Hospital:

℞.—Agaricini (Merck) . . . gr. x.
Atrop. sulph. . . . . gr. j.
Acidi sulph. arom. . . . ♏ 1200.
Dissolve and filter.

Dose—♏ x, containing $\frac{1}{12}$ gr. agaricini, $\frac{1}{1\,2\,0}$ gr. atrop. sulph. and ♏ x arom. sulph. acid. To be administered in syrup or simple elixir.

It may also be advantageously given in pill form, combined with Dover's powder. Thus:

℞.—Agaricini . . . . . gr. ij.
Pulv. Doveri . . . . . gr. xxv.—M.
Ft. pil. No. xx.
Sig.—One pill five or six hours before retiring or sweat comes on. Its action is slow, hence the necessity for giving it early.—*Quarterly Bulletin*, April, 1887.

BACTERIA PECULIAR TO CHILDREN'S DISEASES.—VICTOR BABES, of Budapest, in post-mortems upon children has found in most cases of diseases generally fatal pathogenic bacteria, not like those already described, most of them streptococci and saprogenous bacilli.

In scarlatinal nephritis, in addition to other bacteria, chain bacteria were found closely resembling those of erysipelas. Inoculation in a rabbit's ear with those germs proved rapidly fatal, the animal presenting a widely diffused erythema, closely resembling the eruption of scarlatina. Cultures of these bacteria become rapidly innocuous. Scarlatina is probably caused by these bacteria; as Löffler, Heubner, and Fränkel have thought.

In a case of ceratomalacia a bacillus was found which produced in cultures decomposition, and when inoculated produced disease in mice and rabbits. Microscopical examination of the intestines in cases of dysentery revealed small curved bacilli in the mucous membrane and glands, and also in the organs of the body. When transplanted into agar they grew rapidly and liquefied gelatine. Mice were killed by inoculation, and germs were found in them which grew upon agar: in rabbits, inoculation produced a hemorrhagic, intestinal inflammation resembling dysentery.—*Centralblatt für Kinderheilkunde*, No. 4.

THE DEVELOPMENT AND PRESERVATION OF THE BACILLUS OF TYPHOID.—POUCHET read a paper before the Academy of Medicine of Paris at its session of April 26th, in which he gave the following conclusions:

The conditions of life of the bacillus are within such narrow limits that its destruction is accomplished by many agencies; its proliferation is also arrested by many

constituents of organic bodies. Cultures upon peptonized gelatine abound in bacilli in proportion as the amount of peptone is small: they generally disappear at a proportion of one per cent. Salts of copper, potassium, and ammonium hinder the development of the bacilli; this is also true of acids. A saccharine or albuminous liquid is a bad culture medium.

A gelatine of the following composition,

Distilled water	1000 parts.
Neutral tartrate of potash	1 "
Sugar	20 "
Phosphate of ammonium	1 "
Sulphate of magnesia	½ "
Extract of flesh	25 "
Gelatine	150 "

in which the greater part of the microorganisms contained in water proliferate with activity, does not permit the development of the typhoid bacillus, but the germ preserves its vitality and proliferates energetically if a good culture medium is added (bouillon of intestine, for example), which has been previously inoculated. The typhoid bacillus persists and develops better in pure water than in foul.

The best culture medium is a nutritive gelatine prepared with bouillon, made like a veal broth, from intestine cleared of fecal matter by lavage. In such material the proliferation is very active, and the cultures better than in any other medium.—*Progrès Medicale*, May 7, 1887.

A Rectal Injection for the Convulsions of Children.—Simon advises the following:

Musk	gr. 3.
Camphor	gr. 15.
Chloral hydrate	gr. 8.
The yolk of one egg	
Distilled water	℥ 5.

The intestine should be first emptied by an enema of oil.—*Les Nouveaux Remèdes*, May 8, 1887.

The Dietary of Children Inheriting a Tendency to Phthisis.—Dr. J. Milner Fothergill writes as follows in the *Journal of Reconstructives* for April, 1887:

A wise and proper dietary in the nursery would have saved many a consumptive now slowly perishing, fighting a losing fight, in the Yellowstone region, the high Swiss valleys, along the coast of Florida, or in the Riviera or Egypt. The farmer always believes in the young cattle that have been liberally fed, or, in bucolic phrase, "well done to" in early calf life. As a physician who has had special opportunities of seeing phthisis, I prefer as patients those who have been judiciously reared in the nursery, when any risky phthisis is looming up. To supply fat to the growing organism sometimes a little cunning is necessary. The child does not like even the sight of a piece of animal fat, it revolts at the mere appearance, much less ever tries to eat it. The sweet slice of fat so toothsome and acceptable to those of stronger digestion and more capable assimilation, is repugnant to these more delicate organisms. Let that be the second fact to be borne in mind in the reformed dietary of the nursery. Fat must not be offered in visible, tangible form, except as butter. It must be hidden. The potatoes must be mashed with liberal quantities of milk and butter warmed, if cream be beyond the purse. Then finely minced fat must be liberally supplied to the suet pudding (which is all the better for having some treacle in it—just enough to give it a light cinnamon-brown hue). Bread and butter pudding is an admirable nursery food. When the milk pudding is being served it is well to stir in a good lump of butter; though it must be admitted that this is detrimental to its appearance. But, surely, where is the mother who would weigh her child's existence and the appearance of a nursery pudding in the same scale? Perish the unnatural thought! Where economy is the order of the day, rice stewed with cracked bones is at once palatable and highly nutritious.

Where the assimilative powers are very feeble, then the milk pudding should be made with farina that has already made the acquaintance of heat. It is well to make it of broken biscuit. If made of equal parts of broken biscuit and ground malt, the resultant product is an ideal food, and those readers who are not prepared to take this upon trust and require something more than my unsupported word for the fact, had best forthwith try it, and let "the proof of the pudding be the eating." One proviso, however, it will in prudence be well to put in, viz., there are some palates to which malt is distasteful; and, of course, to these the pudding is a failure. And then let another fact be borne in mind by the food reformer presiding over the nursery, and it is this: malt sugar is not so distinctly and powerfully sweet as is cane sugar or beet sugar, but its flavor is finer; on the other hand, it does not nearly so easily undergo the acetous acid fermentation. Two great matters are involved in this: (1) acidity of the stomach, and (2) dental caries. Cane sugar decomposing into acid, is most favorable to the development of dental caries. The delicate children who are likely sooner or later to die of phthisis in some of its forms, are prone to bad teeth. The imperfect dentine is soon eaten away. Bad teeth interfere with mastication, and so are a fertile source of indigestion; while phthisis is a malady of imperfect nutrition.

Where only small meals are or can be taken at once little interludes are desirable. They should not consist of ordinary sweets made of common cane sugar, but rather of a draught of milk sweetened by malt-extract, a dry malt preparation, or the homely treacle. What unconscious genius introduced treacle into the nursery dietary? Male or female, no trace remains; and yet that individual has been the savior of many a little mite. Treacle has rather sank in public estimation of late years. It is cheap, and therefore of doubtful reputation. It is certainly rather a troublesome thing to handle; and, as our delightful friend, Oliver Wendell Holmes, says, it is not very easy to pour out the last of the contents of a jug—when the contents are treacle. But granting all this, treacle has its good qualities. As said before, it is a capital addition to a suet pudding. Treacle and butter in the centre of a plate of porridge have their attractions. Yes, and their memories, too, gentle reader! Then, in combination with butter, it makes toffy. A marvellous concentrated food is toffy, and an extra ration of toffy in cold weather is an excellent practice. As simple body-fuel to keep up the lamp of life toffy is an excellent food. Rations of toffy are far more acceptable than spoonfuls of cod-liver oil. Some time ago, when on the committee of the West-

moreland's Society School, I put this view forward, and the experiment of toffy in cold weather was tried and found to work capitally, the health of the children being most satisfactory; while, it is almost needless to say, the children approved of it. When toffy is suggested for a fastidious child, which loathes fat and dislikes cod-liver oil, a derisive smile breaks over the countenance of the mother. It is ignorance sneering at knowledge! Knowledge can afford it. But, prejudice and ignorance to the contrary, notwithstanding, toffy is an admirable combination, and has done yeoman service to many a delicate child, as my hospital experience can testify.

Cocaine and Borated Cotton.—Cotton prepared after the following formula is very useful in burns:

Solution of cocaine, 2 per cent.	30	parts.
Boric acid	2	"
Glycerine	4	"
Carbolic acid	1	"
Absorbent cotton	30	"

Dissolve the boric acid in glycerine, add the cocaine solution, and to this add the carbolic acid. The cotton should be thoroughly soaked in the mixture, and dried in a current of warm air.—*Les Nouveaux Remèdes*, May 8, 1887.

Expulsion of the Uterus during Parturition.—Francisco, of Madrid, reports the following case:

A primipara, aged twenty-three, previously in good health, commenced a normal labor which continued until the head entered the excavation of the pelvis. Suddenly, after a violent pain, the uterus was expelled from the pelvis, the os remaining undilated, and the vagina being completely inverted.

While the medical attendant and his consultant were deliberating as to the plan of action, two uterine contractions expelled a well-developed female child. Two deep lacerations were produced upon the left side of the vagina.

After the ligation of the cord, and the removal of the placenta, the uterus was replaced and retained by a bandage.

Complete and uninterrupted recovery followed.—*Gazette Hebdomadaire*, No. 10.

What Cases of Phthisis are Curable by Climate.—Dr. Lindsay writes as follows in the *Lancet* of April 30, 1887:

Speaking generally, only chronic cases with fair reaction are suitable for climatic treatment. If the disease has a well-defined onset and threatens to run an acute or semi-acute course; if the patient steadily loses ground and shows no gain in weight or other sign of rally under treatment; if the process in the lung is progressive and there are no evidences of repair—in each and all of these cases the interests of the patient will be best served by vetoing climatic treatment. The patient will die soon and die anywhere, and he may as well be allowed to pass his last days amidst the comforts and sympathies of home. Cases marked by circulatory weakness, with fast, feeble, fluttering pulse, slight cyanosis, and persistent coldness of the extremities, are very unfavorable for climatic treatment, and should on no account be sent to the mountains. Cases in which laryngeal or intestinal ulceration or renal complication has supervened upon the ordinary type of the disease should be allowed to die at home. Cases in which anæmia appears early and is well marked are unlikely to respond to climatic treatment. On the other hand, we see a vast number of cases of phthisis in which the onset is very gradual and the constitutional involvement for a long time slight. Such cases nearly always improve, even in this climate, under a system of high feeding, fresh air life, and cod liver oil, and I entertain no doubt that a considerable proportion of them may be completely cured by removal to a suitable climate and the adoption of a prudent mode of life.

Antipyrin in Otalgia Nervosa.—Gomperz, of Vienna, reports good results from his use of antipyrin in doses of from fifteen to twenty-five grains in seven cases of uncomplicated nervous otalgia. One of the cases was double, had persisted more than a month, and was cured by fifteen grains of antipyrin. Another took thirty grains. All were improved.—*Wiener med. Presse*, May 1, 1887.

Treatment of Gastralgia.—Gallard advises the following treatment:

Before each meal a drop of this mixture on a lump of sugar.

R.—Morph. hydrochlorat.	grs. 1½.
Aquæ lauro-cerasi	♏ 75.

At the end of a month replace the morphia by one of the following pills:

R.—Ferri arseniat.	grs. 1½.
Extr. valerian.	grs. 75.—M.

Ft. pil. 50 in num.

The treatment should be thus alternated month by month. While using the solution a spring-water containing iron should be drunk at meals. While taking the pills wine or carbonated water should be taken.

Two hours after dining a teaspoonful or tablespoonful of the following should be taken:

Potassii bromid.	℥ 2½.
Syr. aurantii cortic.	℥ 5.—M.

Cold shower-baths, of fifteen seconds, may also be used.—*Les Nouveaux Remèdes*, May 8, 1887.

Treatment of Palpitation of the Heart.—Dr. Benjamin Ward Richardson writes as follows in the *Asclepiad*, No. 14:

During an attack of acute cardiac palpitation, medical treatment of a direct kind can only be palliative. It is a common practice to place the patient in the perfectly recumbent position, but as this position leads, frequently, to breathlessness and much discomfort, I never enforce it unduly. The sufferers usually find out the best position for themselves, and standing up, and even gentle walking backward and forward, commonly appear to bring relief, as if the general muscular action equalized the local over-action.

For the actual palpitation, digitalis is the only remedy I have found of any positive service, and it combines well with remedies which have a tendency to promote, quickly, the cutaneous and renal excretions. I usually

prescribe the tincture of digitalis in five or ten minim doses, with half a fluidrachm of nitric ether, and two fluidrachms of the liquor ammoniæ acetatis. In instances where there has been prolonged sleeplessness with palpitation, I have combined morphia in full doses with digitalis with good effect, adding the narcotic dose to the formula just named.

In general treatment I am accustomed to follow, whether the heart be organically sound or unsound, the same methods as those described in my previous essay on intermittency. The organic bromides of iron, quinine, and morphia, and the mixture of iron carbonate, ammonia, and morphia, are excellent remedies. The only difference in treatment, in fact, relates to the use of alcohol, which, valuable in some cases of intermittency, is less compatible in cases of palpitation.

A FORMULA FOR THE TREATMENT OF TÆNIA TONSURANS:

Olive oil	30 parts.
Precipitated sulphur . . .	4 "
Oxide of zinc	4 "
Carbolic acid	1 "

To be used with frictions morning and night upon the shaven skin.—SÉE, in *Gazette Médicale de Nantes*, May 2, 1887.

COCAINE IN OBSTETRICS AND GYNECOLOGY.—DABBS writes as follows in the *British Medical Journal* of April 30, 1887:

1. I obtained equally good results from a 6 per cent. solution as from a 12 per cent. solution of the hydrochlorate), but in dry labors I now always use a 4 per cent. solution of the alkaloid itself in castor-oil. Into the thin, parchment-like os I put a cocaine-saturated plug of cotton-wool, which I renew (or rather replace with a fresh plug) about every half-hour, until fair dilatation has taken place.

2. In cases in which the labor progresses so slowly that assistance is needed, and the cocaine need not as yet be deposed in favor of chloroform, the form in which I have found ergot of most benefit has been as a hypodermatic combination of sclerotic acid, $\frac{1}{10}$ of a grain, and bimeconate of morphine, $\frac{1}{4}$ of a grain. By means of Burroughs's tabloids, I have been thus able to secure a certain degree more of uterine action, and with the bimeconate of morphine combined with the sclerotic acid and the internal application of the cocaine, have now seen many cases of almost absolutely painless dilatation of the os.

3. But of all uses for cocaine in connection with first labors, I have obtained the most gratifying results from the application of a 12 per cent. solution to the vulva and inside of the vagina during the slow progress of a case of marked perineal rigidity. I do not, of course, mean that the case is hastened much, but I do mean that the pain is lessened to an extraordinary degree.

4. My observations lead me to conclude that it is chiefly in primiparous (slow) labors that cocaine is of use (notably in breech cases), or in any case possibly in which the os dilates slowly and the perineal rigidity is well marked.

5. In cases in which the os has to be dilated by tents, I have soaked and partly enlarged the tents in a hot oleaginous solution of the alkaloid before introducing them, with, as I think, considerable success; and in cases of tender and irritable vaginæ in which, for any reason, the speculum has to be used (gynecological cases), I have adopted the practice with great advantage of previously painting the vaginal walls with the solution of cocaine in castor-oil before alluded to.

POWDERED RICE AS A STYPTIC.—According to the *Indian Medical Gazette*, powdered rice has marked hæmostatic properties. It is said that if mixed with lint in proportion of from ten to eleven per cent., the lint thus treated being used as a compress, it is more effectual than oxide of lime, subnitrate of bismuth, salicylic acid, or carbolic acid.—*Technics*, May 17, 1887.

AN APPLICATION FOR WARTS.—

R.—Hydrarg. bichlorid. . .	gr. 15.
Collodion	$\mathfrak{Z}$ $7\frac{1}{2}$.

Solve.

A small quantity is to be applied to each wart once daily.—*Journal de Médecine de Paris*, May 23, 1887.

A DIAGNOSTIC POINT IN THE DIFFERENTIAL DIAGNOSIS OF HYSTERIA AND INTRACRANIAL TUMORS.—DR. BYROM BRAMWELL writes as follows in the *Edinburgh Medical Journal* for May, 1887:

In dealing with cases of this description, it is essential to remember that the diagnosis of mere hysteria (nothing more than hysteria) is never justified unless the observer has, by the most careful examination, and by repeated observation, failed to detect any symptoms and signs indicative of organic disease.

The condition of the optic disks is, without doubt, the most important point in clearing up the diagnosis. If ophthalmoscopic examination shows the presence of double optic neuritis, the doubts and difficulties of the case are at once removed, for double optic neuritis is very rarely, if ever, associated with mere hysteria, but is very frequently, indeed generally, associated with cerebral tumors.

INTRAUTERINE DOUCHES OF SUBLIMATE.—DR. BERRY HART expressed the following views at a recent meeting of the Edinburgh Obstetrical Society:

It is of use to practise intrauterine douching where parametritis exists. When fixation of the uterus is present, it may not be due to sepsis, but may only be inflammatory. Dr. Hart mentioned a case where the uterus was fixed, and the patient was dying of septicæmia, but was saved by the use of corrosive sublimate. When the mischief is beyond the uterus, abdominal section should be performed, and intra-abdominal douching practised. Corrosive sublimate is as safe as chloroform, if properly used. No man has a right to use it as strong as 1: 1000 in the uterus. It was quite possible that in those fatal cases where a low strength had been used, that the kidneys had been previously affected. Dr. Stevens, in his observations on the urine of patients in the Maternity, had found that in nearly every case the urine contained some albumen. The question arose, Will douching with corrosive sublimate not set up kidney mischief in these cases?—*Edinburgh Medical Journal*, May, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 2, 1887.

THE OPERATIVE TREATMENT OF INTESTINAL OBSTRUCTION.

AT the last Congress of the "Deutsche Gesellschaft für Chirurgie" the discussion upon the operative treatment of intestinal obstruction was introduced by PROF. MADELUNG, of Rostock, in an interesting paper, who restricted himself, however, to the consideration of acute internal strangulation of the bowel. He called attention to the fact that notwithstanding almost every medical periodical contains articles upon this subject, and that it has claimed the attention of all the large societies, still professional opinion is not at all unanimous in regard to the treatment of this condition, and that those who favor laparotomy do not concur as to the indications for the operation; nor have statistics brought about any essential results. In many cases the diagnosis is absolutely in the dark, and can only be determined after the abdomen has been opened, a fact which is painfully true in the experience of every one who has had to treat these troubles. On account of this uncertainty in regard to the diagnosis, we cannot classify cases according to anatomical forms previous to exploration of the abdominal cavity; hence laparotomy affords the only means of advancing our powers of diagnosis. We think every one must agree with these statements, which hold good especially for internal strangulations:

We believe that in the vast majority of cases it is absolutely impossible to reach a certain diagnosis except by opening the abdomen, and that when this has been done, anatomico-pathological conditions will often be found which would have negatived any other line of treatment.

The difficulties and dangers of laparotomy must not be underestimated; in some cases the procedure is simple enough, in others its successful performance will necessitate the exhibition of the highest degree of skill, and in others conditions may be found which no skill can overcome. Madelung gives as the prerequisites for the performance of laparotomy, a skilful operator, rigid antisepsis, and efficient assistance, and states that these qualifications are found only in a well-conducted hospital. When these conditions are not attainable, he recommends that a small incision be made, and an enterostomy performed, an operation which he is disposed to think preferable to laparotomy in many cases. He denies that the statement of Dieffenbach holds equally good in regard to laparotomy as it does with herniotomy, namely, "Every physician must be able to perform herniotomy in any case and in any place." We should be very sorry to accept these dicta as invariable rules of practice. In a thickly settled country like Germany it may be possible to find these qualifications in every case, but in sparsely settled localities they are not accessible, and still the patient should be given the chances which an operation would afford. We can hardly suppose that Ephraim McDowell possessed to any great degree any of these prerequisites when he, for the first time in the world's history, deliberately opened the abdomen for the removal of an ovarian tumor. Still one should be as far as possible prepared for the work by an appreciation of the dangers and difficulties, and by an acquaintance with the means of combating them.

In order to avoid the aspiration of fecal matter during the act of vomiting, whilst the patient is in a condition of narcosis, Madelung recommends the previous irrigation of the stomach, according to the method of Kussmaul.

Considerable space is devoted to the consideration of the question whether a large or small abdominal incision is preferable, and the pros and cons are impartially stated. The disadvantages of the large incision are the danger of the prolapse of the intestines, and the cooling of the peritoneum thereby. Nevertheless KÜMMEL advocates the free incisions, but MIKULICZ recommends a small incision, and seeks to discover the obstruction by the touch alone. Madelung favors an incision of sufficient size to allow the search to be made both by sight and touch, and in this we think he shows wisdom, as it is very difficult to differentiate the parts by touch alone. There is greater danger of sepsis, but this can be avoided by care.

When the distended intestines have escaped externally, it may be impossible to return them until their contents have been somewhat reduced, and this may be effected by puncturing with a fine trocar, but this is of but limited applicability. MR. J. GREIG

Smith, of England, makes the statement that distended coils should never be replaced until they have been relieved by incision and subsequent closure of the openin with sutures. These methods would seem to be too dangerous for routine practice, but in cases of extreme distention it is recommended to incise the bowel and allow its contents to escape. When the bowels are much distended Madelung protests against primary laparotomy, and proposes instead that the stomach should first be washed out, then a small abdominal incision made and a coil of intestine drawn out and fixed with two ligatures; the abdominal incision is then to be tamponed with iodoform gauze, and the bowel opened, the feces allowed to escape, and the intestinal incision sutured; the wound is then to be enlarged, and the cause of obstruction sought for.

In the abstract of this address which appears in the *Wiener med. Wochenschrift* of April 23d, no mention is made of distention of the bowels as a means of quickly reaching the seat of the disease, or of the reddening of the same. If, when we open the abdomen, the intestines are distended, and the distention constantly increases as we draw upon the coil, we may be sure that we are being conducted toward the constriction; but if the distention diminishes, we know we are going away from the constriction; the same holds good in regard to the discoloration from congestion; if it becomes deeper, we are advancing toward the constriction; if it becomes paler, we are receding from it. The seat of strangulation will be found in the right iliac region in a large number cases, hence it is proper to palpate the cæcum to see whether it is collapsed or distended. Sometimes it is necessary to resect a portion of the intestine, and one must judge by the strength of the patient whether it is better to reunite the cut ends immediately, or to form an artificial anus, and subsequently reunite the cut ends of the gut. Madelung was opposed to the immediate union of the bowel, which view coincides with that of some of the most prominent English surgeons.

As the leading principle in the operation, Madelung presents the following aphoristical statement: "The correction of every obstruction can only happen when the eye controls the hand and can accurately follow it. We ought not to operate in the dark." He further states that he is unable to share the hopes of some surgeons in regard to laparotomy, in spite of his unbounded faith in the progress of surgery, but he entertains the hope, however, that in a limited number of cases, by careful selection, stringent antisepsis, and great dexterity on the part of the operator, lives may be saved. Internal strangulations differ from external hernia in that the whole peritoneal cavity forms the hernial sac, and septic germs may wander from gangrenous places and lead to peritonitis, even after the obstruction has been relieved. "The question of the operative treatment of intestinal obstruction is still one of the darkest in the domain of surgery."

In the discussion which followed the reading of this paper, several of the most distinguished German surgeons took part. Rydygier, of Culm, said that the difficulty of locating the seat of the obstruction was frequently the reason why the operation was put off to the last moment, and then any ill result was sure to be ascribed to the procedure. The transient improvement following pumping out of the stomach also excites delusive hopes, and the opportune time for operating is lost. He begged physicians not to waste time with washing out the stomach, but to send the case early to a surgeon. He favored early operations, but was not partial to the formation of an artificial anus, since it leaves the constriction unrelieved, and gangrene is liable to occur.

Czerny's rules for the performance of laparotomy in these cases are that the patient shall be in a fair condition of strength, the belly soft, and the diagnosis moderately certain; in other cases he makes an artificial anus.

Credé, of Dresden, called attention to the fact that acute ileus was frequently preceded by chronic and severe pain in the belly, and he holds it to be proper to operate at this stage, in order to correct the cause of the colic at this early date. "We must not allow it to become ileus." In defence of this proposition, he related three cases upon which he had operated in the colic stage, where false ligaments were found, divided, and the patient cured. This is a bold proposition, and yet it is conceivable that prolonged pain may be an indication for operation.

Mikulicz, now of Königsberg, is inclined to recede from his earlier radical opinions in regard to the necessity of operation, since he has seen three cases recover under expectancy; he holds, however, that when the diagnosis of otherwise irremediable obstruction is made, the operation should be done. He mentioned the very important and very interesting experiments of Czibilski upon dogs, in which it was shown that only salicylic and boric acids could be used safely for irrigating the healthy peritoneal cavity, and that boric solution was not sufficiently effective, whilst sublimate solutions were especially dangerous.

M. Schede, of Hamburg, found but little satisfaction in the consideration of his own experience with laparotomy in acute intestinal obstruction, nor did the literature of the past ten years reassure him. The results are bad. The chief difficulty lies in the diagnosis. One not only cannot locate the seat and nature of the obstruction, but can never be sure that the constriction absolutely requires the knife.

When ileus is ushered in with acute symptoms, collapse, vomiting, and severe pain, laparotomy should be done; but if the collapse is too great, an artificial anus should be made.

From the remarks of those taking part in the discussion, it will be seen that no especially good result has accrued from the consideration of the subject at this time, as there was but little unanimity of opinion in regard to the matter; indeed, the speakers seemed to exhibit less enthusiasm than is common as to the future of the operative treatment of acute obstruction, and some of them actually foreshadowed a greater reliance upon internal treatment than has been fashionable of late. For our part, we believe that these patients should have twenty-four to forty-eight hours of judicious medical treatment, and if that fails, laparotomy ought to be performed at once; that we should not wait until the bowels become gangrenous, or the patient exhausted from suffering or peritonitis, but operate early.

BERGEON'S METHOD OF TREATING PHTHISIS.

On the solid groundwork of experience, as presented in the papers by Bruen, Shattuck, Pepper, and Griffith, which we publish in this issue, we can now obtain an idea of the merits of this treatment. In no instance does it appear to have been curative, as even in the three specially benefited in Bruen's series the local signs persisted. In a variable number of cases relief of certain symptoms has followed, and has possibly resulted from the use of the gas. In a considerable proportion the treatment has been without any influence. Plainly, this method, if applicable at all, does not suit all cases, but we fail to see in the reports any indications as to which cases are likely to be benefited.

The trial, however, has scarcely been a fair one, for all grades and all forms of the disease have been treated in the same way, and we have repeatedly seen patients use the gas whose lungs were honeycombed throughout, and long past any hope of repair. We would urge a further trial in, say, twenty carefully selected cases of incipient phthisis, with the disease limited to an apex, but with signs of undoubted softening, and of bacilli. Such a group could be readily obtained in the wards of the Philadelphia Hospital, and would, if followed for six months, properly test the value of the plan.

Recently, at the Societé Anatomique de Paris, Cornil and Bergeon presented the results of an interesting experiment. Six rabbits were submitted for twenty minutes at a time, during five days, July 23 to 31, 1886, to an atmosphere charged with powdered tubercular sputum. Two died, at Paris, of broncho-pneumonia within ten days. A third was kept at Lyons, and died on the 7th of August, with fever and rapid emaciation. The lung showed one small excavation. No mention is made of any tubercles. The other three were given injections of gas three times a day for thirteen days. As the animals seemed so well, the treatment was not continued. One was killed on the 16th of October, and presented caseous nodules in the lungs, in which bacilli were found. The second one was killed at the end of December, and also showed caseous nodules, and a few tubercles, but not so many as in the first animal. The third was killed on April 27, 1887, and presented a few semi-calcified tubercles. These animals had grown and thrived, and appeared in perfect health. It is claimed that the medication arrested the course of an acute pulmonary disease, since, as a rule, rabbits exposed in an atmosphere containing tuberculous sputa die within two months.

The confirmation of these results would justify a further trial of the enemata in the early stages of the disease, in which alone we may expect benefit.

GENERAL PARALYSIS AND MENSTRUAL DISORDER.

Some years ago Berthier published an interesting monograph, *Des Neuroses Menstruelles*, in which 242 cases of these neuroses were presented, 4 of them being instances of general paralysis following amenorrhœa, in one of which the suppression occurred normally and recently. More recently Petit, in the *Archives de Tocologie* of April 30th, concludes, from the study of fifty-nine cases of general paralysis in women, that there is an intimate relation between this disease and disordered menstruation. He believes that the development of general paralysis in women most frequently causes these disorders. They are characterized in some cases by a sudden and final arrest of the menses, and in others by a remarkable irregularity of the periods which had hitherto been normal. In the cases from which he draws these conclusions, menstruation was normal in only seven, and disordered in fifty-two.

In the light of such facts, it still seems doubtful if menstrual disorder should in all cases be attributed to the disease. Probably the most frequent cause of general paralysis, syphilis, is in the great majority of cases also the cause of the following, or of the preceding amenorrhœa. Seventy-five per cent. of cases of general paralysis can be attributed to syphilis, and whenever this disease becomes grave, menstruation is very liable to be disordered, the flow usually being retarded at first, then becoming scantier, and, finally, a protracted or permanent amenorrhœa succeeds. We believe, therefore, that so far as the majority of cases is concerned, in syphilis, rather than in general paralysis, is to be found the explanation of the amenorrhœa so commonly observed in the latter disease.

THE TREATMENT OF SUPERFICIAL NEURALGIAS BY "KATAPHORESIS."

AT the Sixth Congress for Internal Medicine held recently at Wiesbaden, ADAMKIEWICZ, of Krakau, called attention to this method of treating pain occurring in superficial nerve trunks. It consists in the application of chloroform to the affected area, over which in turn is placed a diffusion electrode connected with the positive pole of a constant battery. The circuit is now completed, and the current kept up for two minutes, then gradually decreased until no current passes. Under these circumstances the chloroform passes through the skin by what Adamkiewicz sees fit to call "kataphoresis," and palsies the nerve trunk without producing any inflammation or sloughing of the part. He thinks that this was a measure not only temporary in its benefits, but permanent, and that while a single application was sufficient to relieve any given attack, that three or four applications, one for each period of suffering, generally effected a permanent cure. He also calls attention to what we already know, that such a procedure is necessarily limited to those cases in which the affected nerve is not deeply situated.

The Times of last Saturday says: "The issue of THE MEDICAL NEWS of this date completes the fiftieth volume of that excellent journal. This indicates a quarter century's existence, although it is but a few years since THE NEWS assumed its present form, in which it at once took rank among the ablest and best of the medical periodicals of the country—perhaps the very best of them all, considered as a medical newspaper, that is always abreast of the leading professional topics of the hour."

While fully appreciating this kindly mention by our contemporary, we may be permitted to correct a pardonable error as to our age, into which it was led by inferring that two volumes have been published each year in the past, as at present. THE MEDICAL NEWS was begun in 1843 as a monthly periodical, and the twelve monthly numbers constituted an annual volume up to 1882, when the weekly issue was substituted for the monthly, with two volumes for the year, so that, in fact, THE NEWS is now in its forty-fifth year of publication, and is the third oldest of the American medical periodicals now in existence, *The American Journal of the Medical Sciences* and *The Boston Medical and Surgical Journal* only antedating it.

THE measure, known as the New York County Medical Society bill, has become a law by the Governor's signature. It is ostensibly a bill to codify the bewildering multitude of medical laws that have been piled one upon another since 1806; it is virtually a compromise measure, acceptable to eclectics and homœopaths, as well as the above-named society; and it is, in reality, aimed to crush out clairvoyants and very ignorant quacks.

THE following is an extract from a letter written by Dr. Abraham Jacobi to the Health Board of New York City. It conveys a sharp reminder to physicians and others who are negligent in regard to thorough fumigations after the termination of cases of diphtheria and allied zymotic affections:

"Ann Donnelly is a cook. She was in the house of Lieut. Reed, West Point. She went to New York to bury a child of hers who died of diphtheria at the house of a Mrs. McKee, No. 327 West Forty-third Street, about May 20. About ten or twelve days ago she unpacked a trunk in Lieut. Reed's house in the presence of his children. The boy is recovering from diphtheria; the girl, of five years, died day before yesterday. The cook has disappeared from the house, trunk and all, ready to unpack again somewhere else and go on murdering. If that woman cannot be sent to the State prison for sowing death wherever she goes, can she not be hunted up and stopped from doing mischief?"

There are some who will not be so severe upon Ann, but will be inclined to throw the blame upon the doctor, if there was one, in charge of the first case referred to in the letter.

THE *British Medical Journal* of to-day will state that Dr. Morell Mackenzie has removed almost all of the fungous growth that remained in the throat of the Crown Prince when he left home.

Since the last operation was performed the Prince has caught a somewhat severe cold, the result of which is that his pharynx and larynx are both acutely congested, the parts in the vicinity of the growth being less affected than the others. The local swelling has caused some difficulty in swallowing, but it is hoped that this will soon disappear. The case at present requires the greatest care and will require it for several weeks. In the meantime surgical operations on the Prince's throat will be suspended. The Prince's cold does not worry Dr. Mackenzie.

In another column we give the full text of the report of Prof. Virchow on the microscopical appearances of the growth removed by Dr. Morell Mackenzie at the second operation at Berlin.

DR. EDWARD H. DUGGAN, of Brooklyn, N. Y., lost his life, June 24th, at the hands of an assassin, while engaged upon his daily round of professional calls. He was shot without warning, and without a chance of defence, by a man who had shaken him by the hand while he held in readiness, behind his back, the loaded, murderous weapon. The murderer is reported as a worthless young man, given to drink, and who at one time kept a liquor saloon; he claims to have "a defence" for his act, the nature of which he will not disclose until he shall

be put upon trial. But the soundness of this claim is not generally credited. Dr. Duggan, the dead physician, was in his fiftieth year, in the prime of his activity, and at the height of a well sustained practice. He was a graduate of the Long Island College Hospital, in 1861, and a member of the regular society and dispensary organizations of his section. His murderer has been indicted, and will be speedily brought to trial.

REVIEWS.

NERVOUS DISEASES AND THEIR DIAGNOSIS. A TREATISE UPON THE PHENOMENA PRODUCED BY DISEASES OF THE NERVOUS SYSTEM, WITH ESPECIAL REFERENCE TO THE RECOGNITION OF THEIR CAUSES. By H. C. WOOD, M.D., LL.D. J. B. Lippincott Co., 1887.

A special work on diagnosis is always indicative of an advance in literature, and this book of Dr. Wood's on "Nervous Diseases and their Diagnosis," is a very decided evidence of the activity in this department of medicine. In the introductory chapter, Dr. Wood details the method by which he proposes to study the diseases under consideration, "Hitherto the authors of text-books have travelled from the lesion to the symptoms." In this work the method of study is reversed, and the investigation is carried from the symptoms to the lesion; a very practical change, making the subject much more clear to the general reader.

The symptoms of neurasthenia or nervous weakness are considered so indefinite and fugitive that the subject is tersely discussed in the introduction. This condition is, however, thought to be the "habitual foundation for chorea, hysteria, insanity, and various nervous diseases, but may exist without the superaddition of any of them." The diagnostic symptomatology of nervous diseases is considered in eleven chapters, the last one being devoted to disorders of intellection, in which insanity is fully considered.

It is impossible in a short review to go over the very valuable matter contained in this work, but it goes without saying that Dr. Wood's book should be in the library of every specialist, if not in the hands of every well-informed general practitioner. The only portion of the work which seems deficient is the description and consideration of multiple neuritis, which has now, from increased frequency, become a most important disease to diagnosticate properly. The fact that the German Government has sent out a special commission to investigate the causes, duration, and progress of beri-beri in the East, shows the importance and prominence given to the study of this disease in Europe.

Chapter VII., on exaltation of sensibility, is particularly full and interesting. Under this division the diagnosis of headache is given the most careful consideration, and as the successful treatment of this most prevalent and obstinate disorder depends entirely on a correct diagnosis, this portion of the work will prove valuable to any practitioner.

Dr. Wood has added a very important work to American medical literature, a book which shows progress in the most difficult branch of the profession, and of which he may justly feel a pride in being the author.

SOCIETY PROCEEDINGS.

THE ASSOCIATION OF AMERICAN PHYSICIANS.

Second Annual Meeting, held at Washington, June 2 and 3, 1887.

(Concluded from page 695.)

FRIDAY, JUNE 3D.—MORNING SESSION.

DR. E. T. BRUEN, of Philadelphia, read a paper on BERGEON'S METHOD OF TREATING PHTHISIS.

(See page 2.)

DR. F. C. SHATTUCK, of Boston, then read some CLINICAL NOTES ON BERGEON'S METHOD OF TREATING PHTHISIS.

(See page 7.)

DR. WILLIAM PEPPER followed in a paper on the same subject.

(See page 10.)

DR. H. C. WOOD, after studying the cases treated by this method, came to the conclusion that it was of a certain amount of benefit. The method of employing the gas presents many objections. The sulphuretted hydrogen should accomplish the same results when absorbed by the stomach as when taken up by the large intestine. He had therefore administered the sulphuretted hydrogen gas in carbonic acid water. Water at the ordinary temperature takes up two or three times its volume of sulphuretted hydrogen. This he considered a distinct addition to pulmonary therapeutics. He called attention to the fact that this is not a new method. In connection with many of the sulphur springs of Europe, there are chambers fitted up where pulmonary catarrh can be treated by inhalation of the gas.

DR. BEVERLY ROBINSON, of New York, considered this to be a valuable adjunct to our methods of treatment. The pain which is experienced in many cases may be due to the fact that there are ulcerations in the intestine. These may be present without the existence of diarrhœa. He had now under treatment a case in which tubercular deposits in the lungs are associated with ulceration of the larynx. He thought that this would be a good case in which to observe the influence of the gas on the local condition. The man has received a daily injection for the past ten days. There has not been the slightest change in the appearance of the larynx.

DR. F. FORCHHEIMER had performed the following experiments. He had treated two or three patients in the way recommended for some time. Then he had substituted for the sulphur solution plain water, and continued the injections for a time. He had also given the carbonic acid gas by injection; and, lastly, he had for two weeks treated these cases with the injection of air, using the Bergeon apparatus. The patients in these experiments did not know that any change had been made in the gas employed. So far as he had been able to judge, the patients treated with air did about as well as those treated with sulphuretted hydrogen. It is clear that the introduction of air is not the cause of the pain in the Bergeon method.

DR. J. T. WHITTAKER had used the sulphuretted hydrogen gas both by injection and also by inhalation.

The effects under both methods of administration seem to be the same. It mitigates the cough, relieves the fever, and lessens the night-sweats. It, however, is not a specific.

DR. F. P. KINNICUTT, of New York, read a paper on

ATROPHY OF THE GASTRIC TUBULES: ITS RELATION TO PERNICIOUS ANÆMIA.

He gave the histories of two cases in which the typical symptoms of pernicious anæmia were well marked. At the autopsy in each of these cases nothing special was found in any organ but the stomach. The inner surface of the organ was smooth. Microscopical examination was made of numerous sections removed from different parts of the stomach. Throughout a large extent no trace of gastric tubules was found. In some parts the more superficial portions of the tubules could be found, but the deeper portions could nowhere be made out. There was also seen a peculiar hyaline substance in the shape of tubes and of drops. Numerous irregular cells were seen near the surface of the mucosa. He thought that in this lesion of the stomach is to be found the explanation of a certain number of cases of pernicious anæmia.

DR. FRANCIS DELAFIELD, of New York, said that in these cases of pernicious anæmia it is natural to look for some influence which would affect the general nutrition. In a number of cases marked changes in the mucous membrane of the stomach have been found. The main question is, whether the lesion of the stomach is to be looked upon as a cause or as the result of the pernicious anæmia. He considered the lesion of the stomach as secondary and not primary. If we attribute the anæmic condition to the lesion of the stomach, the condition must be due to a form of starvation; but in many other diseases leading to starvation we do not find the symptoms of pernicious anæmia.

DR. F. P. HENRY, of Philadelphia, said that the cases reported, in connection with other cases which have been recorded, demonstrate that there is a form of anæmia associated with, and dependent upon, atrophy of the gastric tubules. That this condition is primary, and not secondary, is sufficiently attested by the fact that it is not found in any other condition. Such an extreme degree of atrophy had not, so far as he was aware, been found in any other condition. In the case reported by Dr. Osler and himself, there was complete absence of the peptic glands. It is impossible that any form of gastric digestion could be accomplished.

DR. OSLER remarked that there is unquestionably a group of cases of pernicious anæmia in which there are serious lesions of the gastric mucous membrane, although these lesions are not always the same. It is quite impossible to distinguish clinically the cases with gastric atrophy from the cases without these lesions. In a case of two years' standing, although the symptoms were marked, the autopsy revealed no serious lesion of the stomach.

AFTERNOON SESSION.

DR. E. C. SEGUIN, of New York, made

A THIRD CONTRIBUTION TO THE STUDY OF LOCALIZED CEREBRAL LESIONS.

The first case reported related to the location of the facial centre. The patient, a boy of seven years, was first seen in January, 1885. He had been complaining of numbness in the right hand. The right leg and arm were slightly paretic. There was no headache and no aphasia. Shortly after this, clonic convulsive movements occurred in the right cheek, and both eyeballs were turned to the right. This lasted for over two hours. At times the speech was thick. There was no history of serious injury, and there was no evidence of pulmonary, renal, or arterial disease. There was no cranial tenderness on pressure. The tongue, when protruded, deviated to the right. The diagnosis was meningeal adhesion over the precentral region. Iodide of potassium was given in gradually increasing doses until from sixty to seventy-five grains were taken. Early in April of the following year, symptoms of tubercular meningitis developed, and the child died after an illness of three weeks. At the autopsy, the ordinary lesions of tubercular meningitis were found. In addition, there was a patch of adhesion situated over the left precentral gyrus and the caudal part of the second frontal gyrus. This was one inch in diameter. This would indicate that in the human brain the facial centre is in the caudal end of the second frontal convolution.

The second case related to the situation of the leg centre. A patient, aged forty-nine years, suffered with paresis of the right leg and clonic spasm of the right abdominal muscles. There were right hemi-epileptic attacks, the spasm beginning in the abdominal muscles and extending to the arm and leg. These attacks were repeated without loss of consciousness. Paralysis of the right leg and paresis of the right arm developed. There was no aphasia and no choked disk. Attacks of a syncopal character occurred, in one of which the patient died. At the autopsy a large sarcomatous tumor was found involving the cortex of the paracentral region gyrus. Two small nodules were found in the white substance below the principal tumor. This would indicate that the nerve centre for the leg was in the paracentral lobule.

DR. JAMES J. PUTNAM, of Boston, reported a case recently under his care. A man of forty-five, suffering with locomotor ataxia probably of syphilitic origin, suddenly developed convulsions of the right arm and leg, without loss of consciousness and without change in the voice. The symptoms relating to the arm entirely passed away, but the leg never recovered its normal condition. The patient died some time later, and at the autopsy a small hemorrhage was found at the lower edge of the paracentral lobule.

DR. F. T. MILES, of Baltimore, reported the case of a patient suffering with Bright's disease, who suddenly became hemiplegic without the voice being affected. The arm and leg were affected. He rapidly improved, but the leg remained weak. He complained a great deal of a dragging in the shoulder. At the autopsy the only lesion that could be found was a hemorrhage of the size of a bean in the paracentral lobule.

DR. H. M. LYMAN said that some months ago he saw a case in which there was a sudden convulsion without loss of consciousness, the left arm being principally affected. These convusions were repeated. There was a paretic condition of the left arm, which in a few days extended so as to involve the corresponding leg. The convulsive movements of the upper extremity continued to recur. They did not involve the face. The patient

died, and a sarcoma was found on the right side occupying the position of the centres for the arm and leg.

DR. J. J. PUTNAM, of Boston, then read a paper on

THE FREQUENCY WITH WHICH LEAD IS FOUND IN THE URINE; AND ON THE SYMPTOMATOLOGY OF CHRONIC LEAD POISONING.

He reported analyses of eighty-six cases in which the urine had been examined for lead, although no unequivocal signs of lead poisoning were present. The cases were divided into the following groups:

	No of cases.	Lead present.	Lead absent.
1. Number of symptoms not attributable to other causes	11	2	9
2. Neurasthenia and simple mental depression	9	5	4
3. Fine muscular tremor—nervous debility	9	9	0
4. Multiple neuritis—neuritis with chronic myelitis. Spastic paraplegia—multiple sclerosis	19	15	4
5. Locomotor ataxia	3	0	3
6. Progressive muscular atrophy	4	0	4
7. Acute poliomyelitis of the adult	1	0	1
8. Cerebral and cerebrospinal cases	7	6	1
9. Epilepsy	8	3	5
10. Sciatica	2	0	2
11. Vague neuralgias of long standing	4	4	0
12. Profound anæmia	3	1	2
13. Unclassified	6	3	3

The number of cases in these groups is too small to be of statistical value, but may help in the further analysis of the cases and as a basis for further research. Of the 86 cases of which the urine was examined, lead was found in 48, and was absent in 38, and there is good reason for believing that the number of cases in which it was found in the urine does not fully represent the whole number in which it was present in the body.

If from the 48 cases in which lead was found we subtract those in which the patients were known to have been strongly exposed by their occupation, or otherwise we have left 32 to be contrasted with 38 as approximately representing the ordinary exposure of the community.

It is to be remembered, however, that the patients were drawn mainly from the poorer classes of the community, and that some of them came from country towns or villages where the practice of pumping drinking water through lead pipes from a distant well, the end of the pipe resting in the well, is still very common. All such cases that were known were, however, excluded. Taking the evidence furnished by the cases themselves, and seeking to indorse it by testimony drawn from the literature of the subject and by the effects of treatment, we arrive at the following conclusions, which are, of course, only to be regarded as provisional:

1. It is probable that lead may cause neurasthenic symptoms which may exist for a long time without other signs of poisoning.

2. The same is true of fine muscular tremor, especially if associated with debility.

3. The most important conclusion is, lead seems to cause occasionally a greater or less degree of the symptoms classed as spastic paraplegia instead of the usual type of paralysis with atrophy and loss of the deep reflexes.

4. Additional evidence is furnished of the importance of suspecting lead as a cause of vague cerebral symptoms, such as are often due to syphilis.

5. In one case of epilepsy, in a person not predisposed, and where the probable first attack occurred at the age of twenty-five, besides the discovery of lead in the urine, there was a slight weakness and impairment of electrical reaction of the long extensors of the fingers.

Two cases of ataxia with extensive muscular atrophy and other signs of peripheral neuritis were reported, probably due to lead.

DR. I. E. ATKINSON, of Baltimore, read a paper on

THE FORMS OF TYPHOID FEVER SIMULATING REMITTENT MALARIAL FEVER,

which will appear in full in THE MEDICAL NEWS.

DR. WILLIAM H. DRAPER, of New York, considered that many cases diagnosticated as typho-malarial fever were cases of typhoid fever. He thought that the diagnosis of typhoid fever could be usually made in the course of the first week of the disease by attention to the characteristic course of the fever. The nervous symptoms of typhoid fever are of great importance in the diagnosis. In considering a disease like this we should study it in its totality and not in its elementary parts.

The author has spoken of the aid given by quinine in the diagnosis. His own experience confirmed that of others with reference to the use of quinine as an antipyretic in typhoid fever. Unless used in such doses as to produce a certain degree of collapse it is useless. He believes that it did nothing more than to increase the discomfort of the patient. If in five or six days the use of quinine does not succeed in checking the fever, we may conclude that we are dealing with a continued fever of the nature of typhoid.

DR. W. GUITÉRAS had come to a conclusion different from that expressed by the author. These cases present no symptom of typhoid fever with the exception of the continued fever, and this is a strong argument against their being typhoid. These cases are so numerous, as we go further South, that he would class them as a separate disease. He had examined some of these cases of prolonged continued fever of Southern countries post-mortem, and had failed to find the lesions of typhoid fever. At the South there are three diseases—malarial remittent fever at one end, typhoid fever at the other, and between these, cases of the kind described by Dr. Atkinson. His view of this fever is that it belongs to the class of functional fevers. A simple continued fever may be set up by an excessive demand made upon any of the important functions of the body. He had thought that in warm climates, where constant exertion was required on the part of the heat-centres to keep within limits the production of heat, a paralytic condition of these centres might be induced, especially toward the close of a long and hot summer. For this he suggested the name of continued thermic fever. This fever presents none of the symptoms of a malarial affection and is quite common in sections where malaria is unknown.

DR. A. JACOBI, of New York, thought it a mistake to say that those cases in which the fever cannot be broken in five or six days by quinine are not malarial. There are cases of remittent fever that will not be broken by quinine. There is one assistance in diagnosis which he had not heard alluded to, and that was the diazon test

for typhoid fever to me. This has frequently been of much service to him. It is prepared as follows:

Solution No. 1. Sodium nitrate one part, water two hundred parts.

Solution No. 2. Sulfanilin acid five parts, concentrated muriatic acid fifty parts, water one thousand parts.

Add one and one-fifth parts of the first solution to fifty parts of the second.

Equal parts of this mixture and the urine are to be mixed. Then add about sixty or seventy per cent. of aqua ammonia. In normal urine there will be only a slight discoloration, while in urine from typhoid fever there will be a deep purple discoloration. This test is rarely applicable during the first two or three days. It generally can be applied up to the fifteenth or eighteenth day. It should also be stated that in cases of acute miliary tuberculosis the same reaction is obtained.

DR. W. W. JOHNSTON, of Washington, said that it is well known that in places where malaria has largely prevailed, as drainage has improved malarial affections have diminished, and typhoid fever has increased. This has been the case in Washington. It has also been observed in London. The cases of typhoid fever which he had observed may be arranged into three groups: those in which all the symptoms have been present; those in which only one has been present; and those in which all the symptoms, with the exception of the fever, have been absent. He saw no reason clinically for saying that those cases which present the typical temperature of typhoid fever are not cases of this disease.

DR. R. H. FITZ said that a non-epidemic, of an anomalous form of fever, recently occurred in Boston among a number of emigrants. The diagnosis lay between typhoid and typhus fever. It was concluded that they were cases of typhoid fever. One case ended fatally. The intestinal lesions were of the most trivial character; the enlargement of Peyer's patches was no greater than is seen in many cases of enteritis. The lesions were so superficial that it seemed quite probable that they would have disappeared if the case had lived a few days longer.

DR. I. T. DANA stated that some of the cases to which Dr. Fitz had referred found their way to Portland, and one of them died there. The autopsy in this case showed well-defined but incomplete lesions of typhoid fever. He believed that this is what will generally be found, that the atypical cases will present lesions as imperfectly developed as the other symptoms.

DR. W. T. COUNCILMAN, of Baltimore, thought that a simple examination of the blood will enable us to differentiate between the continued malarial fevers and typhoid fever. The organisms found in these cases of continued malarial fevers are very easy to recognize. They are large, crescentic forms, free in the blood, and not contained in the corpuscles. They do not require a high power for their detection.

DR. W. OSLER agreed with the last speaker, that we have in the microscopical examination of the blood a positive means of diagnosis. He believed that in a doubtful case a careful examination of the blood would determine whether it was malarial or not, while a careful examination by culture methods will determine whether or not it is a case of typhoid fever.

He reported three instances in which the examination of the blood aided in the diagnosis. One was a case of continued malarial fever, thought to be typhoid; another was a case of remittent fever, supposed to be typhoid. In both these instances, examination of the blood showed the case to be malarial. In the third instance, the patient had a chill, which was repeated. It was supposed to be a case of remittent fever, but the malarial organisms were not found. The case pursued an atypical course, and when two weeks advanced in convalescence, had a well-marked relapse of typhoid fever.

EXECUTIVE SESSION.

The report of the Committee on the

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was received and adopted, and Dr. William Pepper, of Philadelphia (with Dr. Reginald H. Fitz, of Boston, as alternate), was appointed as the representative of this Association.

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. William H. Draper, of New York.

Vice-Presidents.—Dr. Francis Minot, of Boston, and Dr. J. Palmer Howard, of Montreal.

Recorder.—Dr. William Osler, of Philadelphia.

Secretary.—Dr. Henry Hun, of Albany.

Treasurer.—Dr. W. W. Johnston, of Washington.

The following were elected to *Active Membership:*

Drs. A. V. Meigs, Louis Starr, and J. H. Musser, of Philadelphia; Dr. James E. Reeves, of Wheeling, West Va.; Dr. William H. Whitney, of Boston; Dr. James Stewart, of Montreal; and Dr. N. Allen Starr, of New York.

Dr. John S. Billings, of Washington, was elected to *Honorary Membership.*

Adjourned.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fourth Annual Meeting, held at Baltimore, May 31 and June 1, 1887.

(Concluded from page 697.)

WEDNESDAY, JUNE 1ST—MORNING SESSION.

DR. A. Y. P. GARNETT, of Washington, presented some

OBSERVATIONS UPON THE SANITARY ADVANTAGES OF TIDEWATER, VA., INCLUDING VIRGINIA BEACH, AS A WINTER HEALTH RESORT.

He stated that while no official records of the causes of death in this locality have been kept, the traditions of the inhabitants during the past hundred years, and the observation of intelligent practitioners practising in this region, go to show that consumption is very rare. In other respects this locality is remarkably healthy. The average number of deaths per thousand, from all causes, during the past six years, has been 10.66. The average death-rate in other sections of the State is twelve per thousand. He was disposed to attribute some of the benefits which this locality presents to the proximity of the Great Dismal Swamp, which has an area of three hundred square miles, covered with cypress and evergreen trees. The atmosphere is remarkably dry. The average temperature during the winter months is considerably higher than at other places along the coast.

DR. A. L. LOOMIS, of New York, then read a paper on

EVERGREEN FORESTS AS A THERAPEUTIC AGENT IN PULMONARY PHTHISIS.

It has long been known that similar climates as determined by geographical and meteorological conditions have different therapeutic effects. That there is some relation between the development of organisms and atmospheric conditions, is becoming more and more apparent. We know that cold and high altitudes render the air aseptic, but the degree of cold and the height required, is so great that clinically it is not possible to derive much advantage from this fact. The effect of a purely aseptic air upon ulcerative processes, is not so great as the effect of an atmosphere which is aseptic on account of the presence of antiseptic agents. The belief in the good effect of pine forests in cases of phthisis is quite unanimous, and the author thought that the clinical evidence in favor of their beneficial influence in these cases was unquestioned. The atmosphere in such regions is not only aseptic, but also antiseptic. Such an atmosphere contains considerable turpentine vapor, and we should, therefore, expect it to contain a certain amount of peroxide of hydrogen. It was his opinion that the majority of cases of phthisis die, not directly from the lesions in the lung, but from the secondary septicæmia and pyæmia which are set up. It is impossible to apply to the ulcerations within the lung the antiseptic washing and dressing that is employed in external lesions, but if an antiseptic atmosphere can be obtained we may hope to counteract the secondary poisoning. Such an atmosphere will not destroy the bacilli, but it will accomplish much in the way of arresting the suppurative process. In his opinion, the atmosphere in the region of evergreen forests acts in a manner similar to the antiseptic agents which are successfully used to arrest suppurative processes in other portions of the body, and he thought that in all probability the active agent was the peroxide of hydrogen resulting from the oxidation of the turpentine vapor. While it is not possible for every one suffering with pulmonary phthisis to go to an antiseptic atmosphere, yet it is possible to render the air of any particular locality antiseptic.

DR. S. S. COHEN said that the paper confirmed certain impressions which he had formed from an experience with methods of making an artificial climate. He had had excellent results in the way of alleviation of symptoms in phthisis by the inhalation of terebinthinate substances, especially where this has been associated with the inhalation of peroxide of hydrogen or oxygen. Under these inhalations he had seen laryngeal ulcers cicatrize, especially if they have been previously washed with the solution of peroxide of hydrogen.

DR. E. L. TRUDEAU, of Saranac Lake, then read a paper on

ENVIRONMENT IN ITS RELATION TO THE PROGRESS OF BACTERIAL INVASION OF TUBERCULOSIS,

which appears in full in the July issue of the *American Journal of the Medical Sciences.*

AFTERNOON SESSION.

DR. F. F. SMITH, of St. Augustine, read a paper on

ST. AUGUSTINE AS A WINTER HEALTH RESORT.

He described the geographical and climatic conditions existing in St. Augustine. An abundance of pure water is obtained from sixty artesian wells. This water is charged with sulphuretted hydrogen. Drinking water is obtained by means of cisterns. A complete system of sewers is now being introduced; these will be flushed by the waste water from the artesian wells. The average temperature during the winter months of the past ten years has been as follows: November, 63°; December, 57°; January, 55°; February, 58°; March, 61°; and April, 67°. The average number of rainy days during the winter months for the past ten years, has been thirty-three, but on nineteen of those occasions the rainfall was at night, so that there were really only fourteen rainy days.

The report of the Committee on

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS,

was received and adopted. Dr. A. L. Loomis, of New York (with Dr. F. Donaldson, Sr., of Baltimore, as alternate), was appointed as the representative of the Association to the Committee on the Organization of the Congress.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—A. L. Loomis, M.D., of New York.

Vice-Presidents.—A. Y. P. Garnett, M.D., of Washington, and James T. Whittaker, M.D., of Cincinnati.

Secretary and Treasurer.—James B. Walker, M.D., of Philadelphia.

Councillors.—Drs. E. T. Bruen, of Philadelphia; J. H. Tyndale, of New York; F. H. Bosworth, of New York; F. C. Shattuck, of Boston; and R. G. Curtin, of Philadelphia.

The Association then adjourned.

CORRESPONDENCE.

LETTER FROM FLORENCE.

A Visit to the Maternity—Obstetrical and Gynecological Statistics — Laparotomy—Cæsarean Section — Wax Preparations.

I was very kindly received here by Prof. Chiara, and went through the wards of the Maternity with him. The building is antiquated in appearance, closely surrounded by other buildings, but everything inside seemed to be cleanly and in good condition. The institution has eighty beds for both gynecological and obstetrical cases, no separation of them being made. The upper floor is devoted to unmarried pregnant women, and here midwives are instructed. I saw about twenty-five cases in this ward. On the lower floor are the married cases, and these are attended by the students. I am informed that all bad cases in the city, among the lower classes, are sent to the hospital, and some of them are in very bad condition when admitted, from delay or want of attention. The spray is used during the process of parturition, and after delivery a douche of corrosive sublimate is used and the patient removed to the lying-in ward. The obstetrical record for the current year, up to date, shows 215 cases, among which were 1 case of eclampsia, 4 cases of placenta prævia, 1 Cæsarean section, 18 forceps cases, 3 of them applications at the

superior strait, and 1 perineorrhaphy. The mortality during this time has been 5, 2 from infectious diseases, 2 from ordinary diseases, and 1 "accident," which means, I believe, hemorrhage. Possibly the statistics for the year 1886 may be of sufficient interest to present:

	No. cases.
Interruption of gestation:	
obstetrical	7
medical	11
Eclampsia	6
Placenta praevia	3
Version	11
Forceps:	
superior strait	15
excavation	29
inferior strait	23
Craniotomy	6
Rupture of uterus	1
Cæsarean section	4
post-mortem	1
Artificial removal of secundines	2
Perineorrhaphy	3
Abortion:	
natural	50
artificial	4
Premature births:	
natural	16
artificial	21
Births at term:	
natural	302
artificial	69
Deaths:	
from infectious disease commencing in hospital	6
admitted with infectious disease	4
ordinary diseases	8
accident	2
Total	14
Twins	5
Quintuplets	1

The admissions to the gynecological department during the year amounted to 430 cases. The following were some of the operations performed:

	No. cases.
Laparotomy	19
for diagnosis	4
Hysterectomy	3
Amputation of cervix	7
Removal of polypi	6

Laceration of the cervix is not recognized at all, and of course the operation for it is never performed. This was told me by Dr. Freeman, of Philadelphia, who is at present studying here, and to whom I am indebted for information.

I witnessed an ovariotomy by Prof. Chiara. The tumor was not large and there were no adhesions of consequence. Both ovaries were removed, the second being found to be affected with cystic disease. The operation was conducted under the spray—three apparatus being in operation in different parts of the room. The pedicles were ligated and then divided with the thermo-cautery. The edges of the wound were sponged with a solution of permanganate of potash, dusted with iodoform, and the wound closed by stitches passed through all the tissues of the abdominal wall. Antiseptic gauze and cotton were laid over the abdomen, above these a pad made by quilting shot between layers of stuff, and over all a bandage.

In seeing in the wards a number of cases convalescent after laparotomy, I had noted extreme scar-marks made by the sutures, which I naturally felt inclined to attribute to septic processes. I am now, however, inclined to attribute them to the large size of the needle and sutures used for closing the abdominal wound. Both were much larger than I have ever seen made use of elsewhere.

Italy presents a fine field for the Cæsarean operation, as is apparent immediately to a medical observer as he passes along the streets. Prof. Chiara has had ten cases, five of them at Milan and five here. Two were by the Sänger method, both successful; eight were Porro operations, with two deaths. Dr. Fasola, the assistant at the Maternity, has had one Porro operation—successful.

I left home with the impression that in Italy ether was nearly the only anæsthetic used. Thus far I have found chloroform alone used, but then my observation has been but limited. In the Maternity here chloroform only is used. No accident has occurred under Prof. Chiara's observation; dangerous symptoms occurred twice. Sometimes, but not always, a hypodermatic injection of atropia and morphia is given before such operations as ovariotomy.

No medical man should visit Florence without seeing the anatomical wax preparations, which are of world-wide celebrity and deserve all the encomiums which have been given them. I had considerable difficulty in finding them. They are now in the Museum of Natural History, where they occupy eleven rooms. The bones and ligaments are first presented, then the other systems and special organs, closing with the brain and nervous system. The latter are especially fine, and are surpassed in excellence only, if at all, by the series of preparations showing the genital organs and gestation through all its periods, as well normal as extrauterine. The wax preparations of Tummo representing bodies in decomposition after the plague, of which considerable is said in the guide-books, are not, in my judgment, worth going to see. They are disgusting—the others have an artistic merit besides their anatomical accuracy to make them attractive. These are in the National Museum, in quite another quarter of the city from the others. R.

FLORENCE, May 24, 1887

NEWS ITEMS.

THE ILLNESS OF THE CROWN PRINCE.—The *British Medical Journal* of June 18, 1887, reports the condition of the Crown Prince as follows:

We are able to state that the progress of the clinical features of the case of the Crown Prince thus far confirms, in Dr. Mackenzie's opinion, the favorable deductions which may be made from the report of Professor Virchow which we have received by telegram from Berlin. The delay in the issue of this important document is due to the fact that precedent was opposed to its publication, and that only serious public considerations and some pressure in high quarters in Berlin have overcome this obstacle. The responsibility of the pathological statement rests with the eminent Berlin professor, than whom there is no higher authority. From the clinical point of view, Dr. Mackenzie is of opinion that

the growth has not at all the aspect of malignancy. It has the granular, slightly cauliflower like appearance of an ordinary papilloma, without any sign of infiltration of the surrounding tissues, and at present there is scarcely even a trace of congestion around the base. There was, of course, a good deal of local swelling after the first operation, but in the interval between Dr. Mackenzie's two visits to Berlin, we understand that this completely subsided under the influence of rest and insufflations of astringent powders. The growth occupies about the posterior fifth of the free edge of the left vocal cord, and the rest of the larynx is to all appearance quite healthy. The voice is all but entirely lost owing to the mechanical obstacle offered by the growth to the approximation of the cords. The Prince can just manage to make himself heard by a great effort. He has never suffered from difficulty of breathing, but there was at one time a little trouble in swallowing, which has now disappeared. This was probably, however, unconnected with the disease. Everything seems at present to give grounds to hope for a favorable termination to this important case, the progress of which may be said to be watched with interest by the whole medical world. It will, of course, be self-evident that the full prognosis in such a case must always be a matter of grave anxiety to the most experienced. During the stay of the Crown Prince of Germany in this country, he will be under the care of Dr. Morell Mackenzie, and Dr. Norris Wolfenden will act as resident medical attendant, to carry out the treatment directed by Dr. Mackenzie. Dr. Wegner, of Berlin, has accompanied the Prince as his personal medical attendant.

The following is the text of Professor Virchow's report on the portion of the growth removed by Dr. Morell Mackenzie on June 8th, as published in the *Berliner klinische Wochenschrift*, of June 20th.

The two objects brought to me yesterday by General-Aerzt Dr. Wegner displayed, when examined microscopically, the appearances of a coarse granular papillary outgrowth. Their rounded surfaces had a conglomerate, bluish-white, transparent, shining appearance so far as they were in their natural state, but certain portions which had been exposed to the influence of catechu exhibited a dull, brownish, somewhat crumbling appearance. The portions removed at the operation were somewhat retracted and hidden by the rolling inward of their edges (*etwas retrahirt und durch das umbiegen der Randtheile verdeckt*). They consisted of a soft, fibrous tissue, from which shorter and longer shreds projected. The larger of the two pieces was 3 millimetres long and 2.5 millimetres thick; the smaller was about 2 millimetres broad and thick. But these measurements probably do not accurately represent the natural dimensions, as the particles have diminished in size, owing to the retraction and to the folding of the sections after their extirpation. Microscopic investigation confirmed the diagnosis arrived at from the naked-eye examination. 1. The surface consisted everywhere of a very thick and dense membrane, with stratified epithelium cells. In many of the cells gelatinous granules of large size were visible; here and there lay a nest of cells lying in concentric layers. Toward the inside there was a similarly stratified layer of cylindrical cells (without cilia) implanted directly on the connective tissue. 2. The surface of the mucous membrane was covered with long papillary excrescences, which, besides the elements of the connective tissue, contained rather large vascular loops (*Gefaessschlingen*). Each nodule visible to the naked eye on the surface was formed by a papilla of this kind. As for the rest, the mucous membrane exhibited scarcely any modification; larger granular and cell-growths were only noticed in scanty quantities; the bloodvessels were only moderately dilated. Both portions removed (*schnitte*) included not only the mucous membrane, but extended through it into the submucous membrane. Hence, besides connective tissue with numerous fine elastic fibres, there was a large number of nerve bundles (with from four to six fibres) and their branches, and of small arteries and veins; at some spots there were masses of the lobules of the mucous glands. Although it is proved by this that the incision reached parts situated deep below the mucous membrane, not a single spot that had undergone any appreciable change was discovered, depite the most careful examination of these more deeply situated parts, especially on the extirpated side. All the essential changes affected the surface only. They prove that the tumor is an epithelial growth associated with papillary excrescences (wrongly described as papilloma), an affection termed "pachyderma verrucosa." At no point was the mucous membrane found to be invaded by the epithelial formations. The specimens now before me are of considerably greater scientific value than that laid before me on May 21st; in the particle then examined only scanty lesions of an irritative kind were seen; lesions only distantly to be compared with those found in the particles now examined: in all, probably, the irritative changes affected the periphery of the seat of the disease. It is evident that on the present occasion a more central spot was reached. Although this spot has become affected in a very marked manner, the healthy quality of the tissue on the extirpated portions gives grounds for a very favorable prognosis. Whether such a prognosis be justifiable for the malady considered as a whole cannot be concluded with certainty from the two pieces that were removed. However this may be, there is nothing in them calculated to awaken a suspicion of a further and more serious affection of these parts.

THE MEDICAL REGISTRY BILL OF THE STATE OF NEW YORK.—Governor Hill has affixed his signature to the bill which the New York State Medical Society has been trying for three years to have put on the statute-books, the measure requiring the licensing and registering of physicians. All the schools of medicine finally united this year on the bill which has just become a law. It restricts the list of authorized practising physicians to those already regularly licensed and over twenty-one years of age. Hereafter those who shall be admitted to practice will be confined, first, to those who shall have been graduated from an incorporated medical school or college with the degree of Doctor of Medicine; second, to those who shall have received this degree from the Regents of the University of the State of New York; third, to graduates of incorporated medical institutions in other States and foreign countries which shall have been approved by the institutions in that State. The County Clerk of each county shall keep a registry-book, in which every physician must

register according to a prescribed formula. No person convicted of committing a felony shall be allowed to practise. The penalty for violating the law is $50 fine for the first offence, and $100 or 100 days' imprisonment, or both, for each succeeding offence. The county medical societies are authorized to prosecute any offenders.

A NEW ACT TO REGULATE THE PRACTICE OF MEDICINE IN ILLINOIS.—A bill which has passed the Illinois Legislature and became a law July 1, 1887, requires examination and license by the State Board of Health, with penalties for neglect of the law; regulates the sale of medicines by vendors, and describes a practitioner of medicine in language which covers the claims of mind-healers and a large class of similar imposters. The definition is as follows:

"Any person shall be regarded as practising medicine, within the meaning of this act, who shall treat, operate on, or prescribe for any physical ailment of another. But nothing in this act shall be construed to prohibit service in cases of emergency, or the domestic administration of family remedies. And this act shall not apply to commissioned surgeons of the United States Army, Navy, or Marine-Hospital Service in the discharge of their official duties."

NEW YORK ACADEMY OF MEDICINE.—Active measures are now being instituted toward the erection of a new building for the Academy of Medicine. There is certainly an urgent need for it. The present academy building is altogether too small. It is said that a site has already been selected in a desirable locality, between Sixth and Seventh Avenues, in Fifty-seventh Street.—*Medical Record*, June 18, 1887.

A JAPANESE DEGREE GIVEN TO AN AMERICAN PHYSICIAN.—The Emperor of Japan has conferred the Decoration of the fourth class of the Order of the Rising Sun upon Dr. J. C. Cutter, of Warren, Mass., formerly house surgeon at the Boston City Hospital, in recognition of his services as professor of physiology and comparative anatomy in the College of Agriculture at Sapporo, Yezo, Japan. The order consists of eight classes, and Dr. Cutter is said to be the second American upon whom the order of the fourth class has been conferred. With but a single exception, no order above the fourth has ever been conferred upon an American.—*New York Medical Journal*, June 18, 1887.

SUIT AGAINST THE NEW YORK HOSPITAL.—A suit was recently brought against the New York Hospital by a patient who had been operated upon for cystitis by cystotomy. The damages claimed were $30,000, on account of impotence from injury of both ejaculatory ducts and wound of rectum. The left lateral incision was made. The plaintiff claimed that in consequence of the injury all his semen escaped into the bladder. It was shown by the testimony of Dr. W. T. Bull, the operator, and Drs. George G. Shrady and L. B. Bangs, that such an injury was impossible under the circumstances, and a verdict for the hospital was rendered accordingly.—*Medical Record*, June 18, 1887.

DR. GRAILY HEWITT has resigned the Chair of Obstetrics and Gynecology in University College, London.

DR. KARL PAWLIK, of Vienna, has been appointed Professor of Midwifery and Gynecology at Prague.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JUNE 21 TO JUNE 27, 1887.

SUTHERLAND, CHARLES, *Colonel and Surgeon.*—Granted one month's leave of absence, with permission to apply for an extension of one month.—*S. O. 126, A. G. O., Division of the Atlantic*, June 23, 1887.

SMITH, A. K., *Lieutenant-Colonel and Surgeon.*—Will be relieved from duty at West Point, N. Y., on September 30, 1887, instead of on August 28, 1887.—*S. O. 144, A. G. O.*, June 23, 1887.

ALDEN, C. H., *Major and Surgeon.*—Leave of absence extended to include September 29, 1887.—*S. O. 144, A. G. O.*, June 23, 1887.

BAKEHOUSE, J. H., *Major and Surgeon.*—Granted leave of absence for two months, to take effect about July 5, 1887.—*S. O. 141, A. G. O.*, June 20, 1887.

RICHARD, CHARLES, *Captain and Assistant Surgeon.*—Sick leave extended two months on surgeon's certificate of disability.—*S. O. 138, A. G. O.*, June 17, 1887.

CORBUSIER, JOHN J., *Captain and Assistant Surgeon.*—Granted leave of absence for one month.—*S. O. 143, A. G. O.*, June 22, 1887.

SUTER, WILLIAM N., *First Lieutenant and Assistant Surgeon.*—Designated as medical officer for the Rifle Camp at Creedmoor, N. Y., July 5, 1887.—*S. O. 124, Division of the Atlantic*, June 21, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 25, 1887.

CLEBORNE, C. J., *Medical Inspector.*—Ordered for examination preliminary to promotion as Medical Director.

LEMMON, G. P., *Passed Assistant Surgeon.*—Ordered to Receiving Ship "Franklin," Norfolk, Va.

HORNITZ, P. J., *Medical Director.*—Permission to leave the United States for six months.

HARRIS, H. N. T., *Assistant Surgeon.*—Commissioned Assistant Surgeon in the Navy June 13, 1887.

SLEAK, J. C., *Medical Inspector.*—Detached from Naval Laboratory, and granted three months' leave of absence.

BLOODGOOD, DELAVAN, *Medical Director.*—Detached from Naval Hospital, Norfolk, Va., and ordered to the Naval Laboratory.

BEASLEY, MICHAEL, *Medical Inspector.*—Ordered to Naval Hospital, Norfolk, Va.

BEYER, H. G., *Passed Assistant Surgeon.*—Remain on present duty until September 1, 1887.

HICKSON, C. G., *Passed Assistant Surgeon.*—Remain on present duty until June 30, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING JUNE 25, 1887.

GUITÉRAS, JOHN, *Passed Assistant Surgeon.*—Detailed for temporary duty at Key West, Florida, June 23, 1887.

WASDIN, LEGENE, *Passed Assistant Surgeon.*—Relieved from duty at Marine Hospital, New York, N. Y.; ordered to Marine Hospital, Chicago, Ill., June 23, 1887.

NORMAN, SEATON, *Assistant Surgeon.*—To proceed to Charleston, S. C., for temporary duty, June 23, 1887.

HEATH, P. C., *Assistant Surgeon.*—Relieved from duty at Chicago, Ill., June 23, 1887.

ORIGINAL ARTICLES.

LITHIUM CARBONATE AND SODIUM ARSENIATE DISSOLVED IN CARBONIC ACID WATER, IN THE TREATMENT OF DIABETES MELLITUS.

BY AUSTIN FLINT, M.D., LL.D.,

PROFESSOR OF PHYSIOLOGY AND PHYSIOLOGICAL ANATOMY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK; PHYSICIAN TO BELLEVUE HOSPITAL.

AT a recent meeting of the Therapeutical Society of Paris, Dr. Martineau made a brief communication, in which he stated that for several years he had treated cases of diabetes mellitus with a solution of lithium carbonate and sodium arseniate in ordinary carbonic acid water, to the exclusion of every other medicinal remedy, and with a moderately strict antidiabetic diet. Dr. Martineau claimed that he had cured sixty-seven out of seventy cases of arthritic diabetes by this method of treatment, which he had borrowed from a practitioner now dead, the late Prof. Rouget, of Paris. The communication was discussed by Dr. Dujardin-Beaumetz and others, who regarded the method as so simple and, to say the least, innocuous, that it was worthy of trial.

The preparation recommended by Dr. Martineau was the following. Into an apparatus such as is commonly used in Paris for extemporaneously making carbonic acid water, are put twenty centigrammes of lithium carbonate and a tablespoonful of a solution of twenty centigrammes of sodium arseniate in five hundred grammes of distilled water. The quantity of carbonic acid water used is about one litre. This quantity is to be drunk by the patient during each day, either by itself or mixed with ordinary wine at meals.[1]

The simplicity of the proposed remedy led me to make an effort to test its efficacy in certain obstinate cases under treatment for diabetes. I endeavored first to have the agents introduced into the ordinary siphons of soda-water prepared and sold in New York; but the manufacturers were unwilling to do this, and I was forced to adopt some other method of preparation. It was finally suggested to me to put up the preparation in ordinary beer bottles with patent stoppers which could be replaced after using a certain quantity. This is now done by Mr. Theodore Angelo, apothecary, 460 Fourth Avenue, New York City, who has supplied the patients to whom the remedy has been given. Two of these bottles make the equivalent of the quantity administered daily by Dr. Martineau.

I was not prepared to make a trial of the remedy before the middle of April, and have used it since then in but three cases—a time too short, and a number of cases too small to admit of anything like definite conclusions. However, in the hope of inducing others to make similar trials, I venture to present the imperfect results of my own brief experience.[1]

CASE LXXXV.[2]—An unmarried lady, fifty years of age, weighing 115 pounds. Her weight in health was 140 pounds. The disease was recognized six months before she came under my care.

March 11, 1886. The general diabetic symptoms were marked, and the urine contained 2½ grains of sugar per ounce. The patient was put on an antidiabetic diet, according to my published diet-table,[3] with Clemens's solution of arsenite of bromine, five drops three times daily. March 19th, the quantity of sugar was 7 grains per ounce; March 26th, 14 grains; April 2d, there was no sugar; and April 7th, no sugar. From March 26th to April 7th, the diet was absolutely anti-diabetic, no bread being taken.

June 17. The urine had been free from sugar since April 2d, under the anti-diabetic diet. The quantity was normal, and the body weight had increased by four pounds. The patient expressed herself as feeling "nearly well."

July 28. The diet for several weeks had been very imperfect; the diabetic symptoms had returned, and the urine contained 24 grains of sugar per ounce. From this date until April 15, 1887, sugar was found in the urine at every examination, the quantity apparently varying with the diet. During this time I made ten examinations. The general diabetic symptoms were much diminished in prominence, although they were distinct. The body-weight did not undergo much change.

April 15, 1887. The daily quantity of urine was 45 ounces, containing 20½ grains of sugar per ounce.

16th. With no change in general treatment, the patient was put on the solution of lithia and arsenic, about two pints daily.

26th. The quantity of urine was 37 ounces, containing 8 grains of sugar per ounce.

---

[1] Bulletin et Mémoires de la Société de Thérapeutique, Paris, 30 Mars, 1887, 18e année, No. 6, p. 41.

Reduced to the English standard, the formula would be about as follows:

Lithium carbonate	3 grains.
Sodium arseniate	⅛ grain.
Carbonic acid water	2 pints.

This formula has been published in a number of medical journals. In some it is stated that a teaspoonful of the solution of sodium arseniate is used instead of a tablespoonful. This error arises from a faulty translation of "cuillerée à bouche," which means a tablespoonful. The term for a teaspoonful is "cuillerée café.

[1] The numbers of these cases are made to correspond with the numbers in my book of records.

[2] Journal of the American Medical Association, July 12, 1884.

[3] Flint: Manual of Chemical Examination of the Urine in Disease, p. 85. Sixth edition. New York, 1884.

May 4. The diet had been relaxed. The quantity of urine was 52 ounces, containing 18 grains of sugar per ounce.

12th. The diet had been more rigid. The quantity of urine was 32 ounces, containing 6 grains of sugar per ounce.

29th. The diet had been imperfect. The quantity of urine was about 40 ounces, containing 24½ grains of sugar per ounce.

On May 12th there was some swelling of the eyelids and the quantity of the solution of lithia and arsenic was reduced one-half. On May 14th, 15th, and 16th, the lithia and arsenic were omitted.

The patient was weak and depressed when the treatment with lithia and arsenic was begun. On May 23d, about five weeks after, she felt much better and stronger, with a gain of two or three pounds in weight.

With the exception of the indefinite statement by the patient that she felt better in spirits and stronger, the lithia and arsenic seemed to have produced no marked effects. This patient is peculiarly susceptible to starchy and saccharine articles of food. Under measures of treatment that had been very beneficial in other cases, she has lately shown little or no improvement; and the most favorable view to take of the case is that the disease, under proper dietetic treatment, may not progress rapidly.

Case XCIII.—A gentleman, sixty-one years of age, 5 feet 5½ inches tall, weighing 157 pounds. The disease was recognized fourteen years ago.

November 19, 1886, the patient came under my care. The quantity of urine was 90 ounces, containing 19 grains of sugar per ounce. The diet had been very imperfect, milk and grapes having been taken freely. He was put upon a strict anti-diabetic diet, with Clemens's solution, five drops three times daily, and one and a half ounces of whiskey three times daily. I saw the patient but once and heard of the progress of the case from time to time from his physician in the country.

April 6, 1887. The patient had not been doing well. He had lost thirteen pounds in weight; the appetite had become very poor, and there was great suffering from pains about the chest and in the limbs.

20th. The general condition was about the same, but the quantity of urine was normal, with 6½ grains of sugar per ounce. The patient was then put upon the solution of lithia and arsenic, two pints daily.

May 11. The general condition was about the same, but the quantity of urine was reduced to 40 ounces and it contained no sugar.

19th. It was reported to me that the general condition of the patient was better and that he was stronger. No report was made of the condition of the urine.

Case XCV.—A married lady, sixty-three years of age, of medium height, weighing 155 pounds. At the present time she has been under my care for a little more than three months. The disease was recognized twelve years ago. In health the patient weighed about 200 pounds.

February 9, 1887. The general diabetic symptoms are well marked. The quantity of urine is excessive and it contains 23 grains of sugar per ounce. The patient was put upon the anti-diabetic diet, with Clemens's solution, five drops three times daily.

14th. The quantity of urine was normal and it had so continued up to this date. The quantity of sugar was 13 grains per ounce. The diabetic symptoms had disappeared.

April 4. The urine has been examined regularly once a week and the quantity of sugar has been gradually reduced to one grain per ounce. The appetite became very poor about a week ago, and insomnia was very troublesome, with shooting pains over the liver.

17th. The patient was put upon the solution of lithia and arsenic, two pints daily.

25th. The quantity of urine was about normal and it contained no sugar.

May 17. The general condition has improved. Since April 25th, the urine has contained about one grain of sugar per ounce. Within the past six weeks the patient has lost fourteen pounds in weight.

April 24. The general condition of the patient is much improved. The quantity of urine is normal and it contains about one grain of sugar per ounce.

The general result of the observations on the three cases reported is quite indefinite. The effects of the solution of lithia and arsenic were not well marked, and the slight improvement under its use in Cases XCIII. and XCV. might have been due to other causes. I shall, however, continue the remedy in these three cases and employ it in other cases until I shall have given it a fair trial; but I do not feel that it would be prudent in any case to relax the dietetic treatment.

With other so-called specifics for diabetes mellitus I have had some experience.

I have given calcium chloride in a number of cases with entirely negative results.

In several cases I have used Jambol, also with negative results.

I have never given opium, except for the relief of pain and insomnia; but in cases in which it has been used it has been well tolerated.

I nearly always prescribe at first Clemens's solution of the arsenite of bromine. This remedy does no harm, and in many cases it seems to exert some control over the thirst, polyuria, and the quantity of sugar in the urine.

I invariably interdict the use of milk and skim-milk. In a number of cases, in which it has been taken by patients on their own responsibility, I have observed that it promptly induces thirst, polyuria, and an immense increase in the discharge of sugar. In some instances, in which my published diet-table has been copied, milk has been added. This addition, it seems to me, is most unwarrantable; and the use of milk more than counteracts the beneficial results to be expected from the anti-diabetic diet properly carried out.

For the past three years I have recommended a gluten bread made by George V. Hecker & Co., of New York. This bread at first contained between

two and five per cent. of starch. Within a year, however, it has seemed to act unfavorably. I have lately had a number of analyses made of this bread, and it has been found to contain about thirty per cent. of starch. Within the last two months I have temporarily abandoned its use, although this has greatly increased the difficulties of the dietetic treatment. It is to be hoped, however, that the Messrs. Hecker, who are untiring in their efforts to produce a satisfactory and uniform anti diabetic bread, will soon perfect their process, so that the bread will be entirely reliable. This will require a more simple chemical process of control, the ordinary methods of ultimate analysis for starch being tedious and expensive.

I have not been able to study the details of the seventy cases mentioned by Dr. Martineau, sixty-seven of which he reported as cured.[1]

The experience of all who have followed out any considerable number of cases of diabetes teaches that the disease is nearly always liable to return under a careless diet; and my own experience is no exception to this general rule. That such an exception should have occurred in the experience of Dr. Martineau would, indeed, be remarkable.

Including the three cases already briefly reported, I have now under observation and treatment ten cases which I have followed for variable periods. It may be interesting to compare seven of these cases with the three treated with the solution of lithia and arsenic.

CASE LXXXIII.—A gentleman, fifty-eight years of age, 5 feet 7 inches tall, weighing 156 pounds. I began the treatment of this case January 17, 1886. The disease had been recognized four years before. The patient had been under the care of an eminent English physician, who gave the opinion, after two or three years of treatment, that the disease would never be entirely cured.

January 17, 1886. The diabetic symptoms were distinct, but slight. The patient had been under a moderately strict anti-diabetic diet. The quantity of urine was 60 ounces, containing 2½ grains of sugar per ounce. The patient was put upon an absolute anti-diabetic diet, without any bread, for two days, and Clemens's solution, three drops three times daily, the dose to be increased in five days to five drops. Two days after, the urine was free from sugar. The patient has continued to be perfectly well in every way up to the present time, being very actively engaged in business.

From January 17, 1886, to May 22, 1887, the urine has been examined twenty-seven times. On December 19, 1886, a trace of sugar was found, this being the only examination in which the urine was not free from sugar. The diet was strict, Hecker's bread being used for the first three months. Since then, while the patient has been careful, the diet has been rather liberal, and the patient has not suffered any serious privation.

CASE LXV.—A gentleman, forty-one years of age, six feet tall, weighing 205 pounds. The disease had been recognized six months, and the patient had lost about forty pounds in weight.

April 22, 1885. The patient had the usual diabetic symptoms in a marked degree. The quantity of urine was excessive, and it contained 21 grains of sugar per ounce. The patient was subjected to essentially the same course of treatment as detailed in Case LXXXIII. In four days the urine was found free from sugar, and the diabetic symptoms had disappeared. Between April 22 and December 22, 1885, the urine was examined thirty-one times. August 10th, the urine contained 9 grains of sugar per ounce; September 1st, no sugar; December 10th, 3½ grains of sugar per ounce; December 22d, no sugar. On the two occasions, the presence of sugar was probably due to indiscretions of diet, and it promptly disappeared under a strict regimen. After the first two months of treatment, the diet was but little restricted. Since December 22d I have seen the patient casually from time to time, and he has reported himself as perfectly well.

CASE XCI.—A gentleman, fifty-six years of age, five feet eight inches tall, weighing 166 pounds. Twelve years ago he weighed 200 pounds. Sugar was recognized in the urine eight years before the patient came under my care.

October 14, 1886. The general diabetic symptoms are slight. For the past eight years the patient has been under a very imperfect anti-diabetic diet, and, so far as I can learn, the presence of sugar in the urine has been constant. The urine is now normal in quantity and contains 25½ grains of sugar per ounce. The patient was put upon essentially the same course of treatment as in Cases LXXXIII. and LXV. On October 21st the urine contained 13½ grains of sugar per ounce; on October 26th, 11 grains per ounce.

29th. The patient was subjected to an absolute fast of thirty-six hours, after the method proposed by Cantani,[1] taking, during that time, nothing but water. The fast was borne very well, and on the day following the patient expressed himself as "feeling as well as he had felt in ten years." The quantity of urine during the last twenty-four hours of the fast was 25 ounces, and it contained no sugar. The ordinary antidiabetic diet was then resumed. October 31st, the urine contained 13 grains of sugar per ounce; November 3d, 10 grains. From November 9th to 20th, there was no sugar. On February 23, 1887, I heard from the patient. His urine had been repeatedly examined, and no sugar had been found. He reported that his "general health had been very good."

CASE VI.—A gentleman, about sixty years of age, 5 feet 6 inches tall, weighing 185 pounds. From March 22, 1878, to February 24, 1885, I had repeatedly examined the urine of this patient while he was partly under the care of the late Dr. Austin Flint. From April 21, 1878, to January 10, 1882, the urine was free from sugar. From October 14, 1882, to February 24, 1885, the urine had generally contained sugar, sometimes in large quantities.

[1] A brief account of three cases, treated by Dr. Martineau, is given in the Therapeutic Gazette, Philadelphia, May 16, 1887, p. 330.

[1] Cantani: Le diabète sucré, p. 402. Paris, 1876.

December 15, 1886. The patient came under my direct care. The quantity of urine was about normal, and it contained 18 grains of sugar per ounce. The patient was languid and easily wearied, but had no abnormal thirst. He was put upon the usual treatment, and took no bread. On December 19th, he was much improved. The urine contained $7\frac{1}{2}$ grains of sugar per ounce. The variations in sugar for a few weeks were as follows: December 23d, 6 grains per ounce; December 26th, $3\frac{1}{2}$ grains; January 1, 1887, a trace of sugar; January 8th, a trace of sugar.

May 24, 1887. The patient had been absent from the city from January 12th to May 4th. He now feels perfectly well. On May 4th and 24th, the urine contained a faint trace of sugar. Since December 13, 1886, the patient has taken no bread. The antidiabetic diet has been rigidly carried out, and the appetite has been tempted by skilfully prepared dishes within the limits of the "diet-table," so that the want of bread has not been a serious privation.[1]

CASE XCII.—A gentleman, fifty-one years of age, 5 feet 11 inches tall, weighing 208 pounds. Five months before he came under my care, he was examined for life-insurance, and no sugar was found in the urine. About three months later, there were thirst, polyuria, weariness, etc., and sugar was found in the urine.

October 20, 1886. The quantity of urine was 100 ounces, containing 31 grains of sugar per ounce. The general diabetic symptoms were marked. The patient was put upon the antidiabetic diet and Clemens's solution. On October 27th, the quantity of urine was reduced to 40 ounces, and it contained no sugar. The diabetic symptoms had entirely disappeared. November 4th and 27th, the conditions were the same. The patient then removed to the West. On January 28, 1887, he wrote me that he was perfectly well. On April 28th he wrote that he was as "good as new." Since his removal to the West the urine has been repeatedly examined and no sugar has been found. The treatment has been continued, with slight relaxation in the diet.

CASE LXXVII.—A gentleman, twenty-four years of age, 5 feet $5\frac{1}{2}$ inches tall, weighing 132 pounds.

October 28, 1885. The general diabetic symptoms were marked. The patient had lost twelve pounds in weight within the past three weeks. The quantity of urine was 112 ounces, containing 28 grains of sugar per ounce. The patient was put upon the treatment already described. On January 6, 1886, the diabetic symptoms had disappeared, and the quantity of urine was reduced to 50 ounces, containing 4 grains of sugar per ounce. On May 19th and June 30th the urine contained no sugar. On September 8th, the quantity of urine was 90 ounces, containing $11\frac{1}{2}$ grains of sugar per ounce. The diet had been imperfect for about two months.

March 2, 1887. The urine was normal in quantity, and it contained 9 grains of sugar per ounce. The patient had been eating freely of Hecker's bread, which, as I have stated, probably contained about thirty per cent. of starch.

CASE LVIII.—A gentleman, forty-three years of age, 5 feet 9 inches tall, weighing 204 pounds. The disease is probably of eight or ten years' standing, but sugar was recognized in the urine only one year before the patient came under my care.

November 30, 1884. The diabetic symptoms were marked. The urine was very abundant and contained 6 grains of sugar per ounce. The patient was put upon the treatment already described. On December 13th the symptoms had disappeared, the urine was reduced to the normal daily quantity, and there was no sugar.

July 7, 1885. The patient had been perfectly well. The urine had been examined seven times since December 13, 1884, and no sugar was found. The diet had been well carried out.

September 20, 1886. The quantity of urine was 55 ounces. The morning urine contained $15\frac{1}{2}$ grains of sugar per ounce, and the evening urine 30 grains. The diabetic symptoms had returned in a moderate degree.

October 12. The urine was normal in quantity, and contained $14\frac{1}{2}$ grains of sugar per ounce. The antidiabetic treatment was resumed. The diet had been unrestricted since October, 1885, the patient then regarding himself as cured.

16th. The urine was normal in quantity, and contained $9\frac{1}{2}$ grains of sugar per ounce.

November 16. The urine contained no sugar, and the diabetic symptoms had disappeared. On January 24, 1887, the conditions were the same.

April 13, 1887. The urine contained $1\frac{1}{2}$ grain of sugar per ounce. The patient had been travelling, and the conditions for maintaining an antidiabetic diet were unfavorable. The patient had been eating freely of Hecker's bread.

The ten cases reported are all that are now under my immediate observation. At the risk of being tedious, I have given certain details regarding these cases, although my records have been considerably abridged in this article. These cases seem to me to be quite instructive. Taken in connection with my other recorded cases, they lead me to the following conclusions:

1. In the three severe cases in which I have used the solution of lithium carbonate and sodium arseniate in carbonic acid water, no very marked effects have been observed in the few weeks during which the remedy has been employed; but the treatment seems to me to be worthy of more extended trial, and it may be useful in mitigating the severity of a strict antidiabetic diet.

2. The so-called specifics for diabetes have little if any effect. An exception, however, may be made in favor of the arsenite of bromine, which has some-

[1] In many regards this case is of great interest. Its progress from March 22, 1875, to August 15, 1884, was reported in my article in the Journal of the American Medical Association of July 12, 1884, Case F. On April 15, 1871, while the patient was under the care of Dr Brown Sequard for some slight nervous disorder, I examined the urine and found it normal. I recognized sugar in the urine, March 22, 1875. Under a moderately strict diet the sugar promptly disappeared, and was not discovered again until October 14, 1882, three years and nearly seven months after, although the diet was unrestricted during the greater part of this time. This might have been regarded as a case of transient glycosuria, if the disease had not become confirmed in 1882 and 1883.

times seemed to me to control, to a slight extent, the thirst, polyuria, and discharge of sugar.

3. The main reliance in treatment is to be placed upon an antidiabetic diet. This has fallen somewhat into disrepute because it is seldom efficiently carried out. In no single instance, out of ninety-nine recorded cases, have I found that the antidiabetic diet had been enforced.

4. Milk should be absolutely interdicted. Its influence over the progress of the disease is prompt, powerful, and most injurious.

5. There are certain cases in which dietetic treatment promptly arrests the disease and keeps it under control. There are other cases in which treatment seems to be of little avail, except in possibly retarding the progress toward a fatal result. Of the ten cases reported, and now under observation, seven are amenable to treatment and three are obstinate.

6. A confirmed diabetic may be cured, in the sense that all symptoms will disappear; but the disease is liable to return at any time under an unrestricted diet. Still, moderate care in diet will often secure immunity.

7. A patient who has once had diabetes should have his urine examined every few weeks. The glycosuria always precedes the general symptoms of the disease, and these general symptoms can generally be forestalled by proper treatment employed as soon as sugar makes its appearance in the urine.

8. As the disease returns, either from imprudences in diet or from other causes, the successive recurrences present greater and greater difficulties in the way of treatment.

SYPHILIS OF THE NERVOUS SYSTEM AND ITS TREATMENT.[1]

BY LANDON CARTER GRAY, M.D.,
PROFESSOR OF MENTAL AND NERVOUS DISEASES IN THE NEW YORK POLYCLINIC.

THE task which lies before me to-night is no easy one. It is the task of explaining, within a short space of time, the symptoms that may arise from a disease which affects the whole of the complicated machinery of the brain, the spinal cord, and the peripheral nerves. I cannot hope to do more than outline the subject. To treat it exhaustively would require a book, to which this paper might serve as an introduction.

Some idea of medical interest in the matter may be obtained from a somewhat curious comparison. Professor Max Müller, the well-known philologist, informs us that the whole of the Sanscrit literature, running, as he expresses it, "like a high mountain-path of literature through the whole history of India, and extending over a period of three or four thousand years, is contained in about 10,000 manuscripts"—more, the same authority estimates, than the whole classical literature of Greece and Italy put together.[2] I have been able to count up some 500 different articles that have been written on the subject of syphilis in the last thirty years, and there are probably many more. This is one-twentieth of the whole Sanscrit literature, or of the combined classical literature of Italy and Greece; and, therefore, in order that the literature of this one subject should equal these great national literatures, it would only take the time of about 600 years, or one-seventh to one-fifth of the time of the Sanscrit writings.

Syphilis of the nervous system varies essentially from the syphilis about which the great syphilographers of France, England, and America have written so voluminously, because the phenomena of the disease which they described have been almost entirely confined to the cutaneous surface of the body. When this malady, however, affects the nervous centres and their peripheral appendages, it usually, I am prepared to say, has not been marked in its cutaneous manifestations. Most of the cases I have had the fortune to see had this peculiarity. At the outset, therefore, we are met with one great difficulty, which does not bar the way of the dermatologist—we are deprived of the diagnostic guidance of a group of symptoms which have been carefully studied for many years; and in their place no one has as yet suggested an equally pathognomonic group of nervous symptoms. Unguided by the tell-tale signs upon the exterior of the body, the history of the initial lesion may, as is probably well known to most of you, become very obscure. The primary sore being usually very slight, it may very easily be overlooked, even by those who are in search of it. The infection may come through the husband to the wife, innocently, too, so far as the latter is concerned. Not long ago I heard a lady telling some friends how she had been afflicted with an obstinate headache and subsequent inflammation of the eyes. Now, it so happened that this lady's husband had died a short while before of intracranial syphilis, and on going to her attending physician, I found that he was entirely ignorant of the etiology of his patient's symptoms. The infection may also come through a surgical operation, as is probably known to you; for I suppose that there are very few communities of any size in which physicians cannot be found who have infected themselves in this manner. Or the infection may come through a lesion innocently acquired about the buccal cavity, and even, perhaps, through articles of clothing. Infection through heredity is of no small account. For these different reasons, it may readily occur that many individuals may be entirely unaware of the disease of which they are the bearers. Add to these sources of error the tendency to concealment which so often actuates patients, glandular indurations, exostosis, in hereditary syphilis the peculiar teeth described by Hutchinson, and the record of many miscarriages and dead-births. All these latter incidents may greatly assist us when they are present, which, unfortunately, they are not in a number of cases of nervous syphilis.

At the outset, it should be clearly understood that syphilis may affect the whole of the nervous system—the brain, spinal cord, peripheral nerves, membranes, sheaths, and the bony structures surrounding the nervous tissues, and the bloodvessels within the nervous tissues. It may assume the form of a diffuse infiltration, or it may be limited to a gumma, or it may be confined to the arteries, or there may be

[1] Read, by invitation, before the Philadelphia Neurological Society, April 25, 1887.

[2] India: What can it Teach us? By F. Max Müller, 1883.

diffuse infiltrations, gummata, and arterial lesions in one subject. This diffuse infiltration takes its departure from the capillaries, and consists of numbers of round cells spread throughout surrounding tissues. These are the round cells of the shape of those formations to which Virchow has given the name of granulation tumors, and for which other German pathologists have suggested the name of infectious-granulation-tumors, to which class belong the tubercular formations, lupus, lepra, actinomycosis, and glanders. The cellular character and behavior of each one of these different species are, as is well known, different, as is also their particular location within the body; and two of the salient characteristics of the cells thrown out in a syphilitic infiltration are: that they have scarcely any tendency to suppuration, undergoing a retrogressive metamorphosis by non-suppurative transformations, and that the individual cells are endowed with extraordinarily long-lived vitality. These cells may often lie among the normal tissues for long periods of time and not do any really structural damage. On the other hand, they may set up truly destructive processes that may injure the component parts of a tissue as much as any other destructive process whatsoever.

The arterial lesions were first described in 1874, by Dr. Heubner, of Leipsic, whose observations have given rise to further and often contradictory investigations by Köster, Friedländer, Baumgarten, Rumpf, and many others. Heubner advanced the view that in syphilitic vessels the endarteritis was peculiar in its place of origin, which was in the vessel-less tissue that lies between the *membrana fenestrata* and the endothelium. Normally the *membrana fenestrata* and the endothelium lie so close to one another that no intervening tissue can be seen microscopically. In syphilitic endarteritis, however, Heubner maintains, they are widely separated by a new cellular formation, which consists of a proliferation of endothelial cells, to which, after a certain time, there are added numbers of round cells, as in the ordinary granulation tumors. Heubner very minutely and carefully describes the differences in size of the endothelial cells in health and disease, as well as how to obtain an endothelium that has not been bruised by the ordinary act of cutting the vessel, and it is difficult for any one who reads his painstaking brochure to refuse credence to his plea for this peculiar anatomical site of syphilitic endarteritis, nor is it easy to resist the wish that it were true, as it would constitute so invaluable a guide in dubious cases. But in the thirteen years that have elapsed since Heubner first made his views public, no one has fully confirmed him. Köster, Friedländer, Baumgarten, Huber, Schottelius, Marchand, Rumpf, deny that the endarteritic process starts in the vessel-less structure between the *membrana fenestrata* and the endothelium, or that it consists at first of an endothelial proliferation. They maintain, on the contrary, that the endarteritis is due to the outpouring of round cells from the minute nutritive vessels of the vessels themselves—from the *vasa vasorum*—contained in the outer coats, and that the endothelial proliferation is only a part of the general cellular disturbance that takes place in consequence of this outpouring of round cells. The question needs further investigation. But, however it may be decided, there is no diversity of opinion as to the results which follow upon the endarteritis. The vessels may become narrowed in their lumen by the thickening inward of the fenestrated membrane and the intima. They may become entirely occluded from the same cause. The inner surface of the intima may become roughened or altered in its chemical constitution, and a thrombus may form, which may, in its turn, give rise to an embolus. It may even happen, rarely however, that minute aneurisms may be formed from the wasting of the muscular coat of the vessel, and occasionally there may be a hemorrhage. In other words, a syphilitic infiltration may set up an endarteritis which usually leads to a narrowing of the canal of the vessels, or to an occlusion of it, but which may occasionally lead to thrombi, emboli, aneurism, and hemorrhages.

The prevailing tendency of thought among modern pathologists has naturally led to an endeavor to trace syphilis to a microörganism. As is usual in researches of this kind, our German friends have led the van. As far back as 1869 Hallier thought that he had detected peculiar microbes in the blood corpuscles, and Lustdorfer described syphilitic bodies in the blood. These statements do not seem, however, to have been verified. Klebs, in 1879, Aufrecht, in 1881, and Birch-Hirschfeld, in 1882, described microörganisms which they would have us regard as the cause of the phenomena of syphilis. But the investigations of Lustgarten and Doutrelepont since 1884 have been more precise than those of their predecessors, have been largely confirmed, and have, therefore, attracted far more attention. These gentlemen have described slender bacilli, like straight or somewhat curved rods of about the size of the tubercular bacilli, and they are found singly or in groups in cells. They bear spores, which appear as clear, oval, glittering spots. They are colorable by a method described by Lustgarten. A most energetic discussion of these bacilli, their relations to syphilis and their differentiation from other bacilli, has been and is still going on in France and Germany. The mere catalogue of the disputants will indicate the interest that is felt in the subject—Cornil, Giacomini, Disse and Taguchi (two Japanese medical men writing in German), Klemperer, Köbner, Matterstock, Rumpf, Gottstein, Leloir, Weigert, Baumgarten, Tavel, Alvarez, Eve, Longuard. As a result, it may be stated, that the question is not by any manner of means yet decided; that the bacilli described by Lustgarten have been found by many in syphilitic individuals; that bacilli, similar in some respects to those of Lustgarten, are found in normal smegma and the secretions of the genital organs; that the bacilli of Lustgarten and those of the smegma and the genital secretions differ from one another distinctly in several particulars; that there are probably several bacilli in syphilis, two varieties being described by Rumpf. The bacilli of Lustgarten have been found in all stages of syphilis and in syphilitic alterations in many different tissues, and nothing like them has been found

in non-syphilitic individuals, except in the smegma or the genital secretions, and even here there are alleged points of difference: hence it would certainly seem as if Lustgarten's bacilli bore some relation to syphilis. No one has as yet succeeded in obtaining any pure cultures of these bacilli, and this test is therefore lacking.

So much do we know of the pathology of syphilis.

These diffuse infiltrations, these gummata, these arterial lesions, may, as must be evident to all of you, cause symptoms that are coextensive with the symptoms of derangement of any part of the nervous system. All the recognized mental and nervous disorders may have a syphilitic basis, and in the case of any one of them it simply becomes a question as to whether a history of the infection is obtainable. So far as is known, it is not possible to say of any nervous or mental disorder that it may not have a syphilitic causation; and if we may draw conclusions from the nervous and mental disorders of recognized syphilitic causation, we should say that the prognosis of very few would be materially altered by such etiology. But over and above the well-recognized forms of nervous and mental disease, there are certain groups of symptoms which may fairly be regarded as indicative of specific infection, although the proof may not be greater than that to which the lawyers give the name of "prima facie"—*i. e.*, proof amounting to a presumption, which may, however, be rebutted by adequate testimony to the contrary. These symptom-groups, if I may allowed to formulate from my own experience, are as follows:

1. Quasi-periodical cephalalgia of a peculiar kind.

2. Hemiplegia under forty years of age, with or without preceding cephalalgia of the aforesaid type.

3. Cephalalgia followed by hemiplegia, which bear a singular relationship to one another in that the cephalalgia ceases immediately upon the supervention of the hemiplegia, and does not recur.

4. Convulsions in the adult, which have not been preceded by convulsions in infancy, and are not of traumatic or nephritic origin, or due to pregnancy, or in an individual subject to migraine.

5. Symptoms indicative of a lesion at the base of the brain.

6. A comatose condition extending over days or weeks, not traumatic, meningitic, diabetic, nephritic, or from typhoid fever.

7. Tabes dorsalis.

8. General paresis.

9. Spinal lesions in a subject who has had intracranial syphilis.

1. *Quasi-periodical cephalalgia of a peculiar kind.* One expression of the quasi-periodicity of syphilitic cephalalgia that is well known to the profession is the nocturnal recurrence. But this characteristic may be other than nightly. I have known the headache to recur repeatedly at a certain time of the day, usually in the afternoon. What is very misleading, too, in the way of differentiation of malaria is that this cephalalgia may yield readily, although temporarily, to large doses of quinine. This quasi-periodical form of neuralgia may be accompanied by an obstinate insomnia, and by considerable mental irritability, both insomnia and irritability bearing no adequate proportion to the amount of pain; when the latter signs are present, they are of considerable diagnostic importance, because the cephalalgia of brain tumor or nephritis is not usually accompanied by them.

2. *Hemiplegia under forty years of age, with or without preceding cephalalgia of the aforesaid type.* It is a fair clinical distinction that can be used for guidance of one's inquiry, upon first talking with a patient, to bear in mind that hemiplegia in the adult under forty years of age is usually of syphilitic origin, whilst hemiplegia in the adult above forty years of age is due to the chronic degenerative endarteritis of middle life and old age. Hemiplegia may occur in children, of course, from many other causes, and should, therefore, be ruled out in the present inquiry. This adult hemiplegia of specific origin may be either motor or sensory, or both, for anatomical reasons that need not be explained.

3. *Cephalalgia followed by hemiplegia, which bear a singular relationship to one another, in that the cephalalgia ceases immediately upon the supervention of the hemiplegia, and does not recur.* This is a curious clinical feature to which, so far as I know, no writer has yet made allusion, and one which I have observed in over forty cases, although I can offer no explanation of it whatsoever. I have never seen it except in syphilitic hemiplegia. I should like to ask the attention of the profession to this point, in order that it may be tested.

4. *Convulsions in the adult, which have not been preceded by convulsions in infancy, and are not of traumatic or nephritic origin, or due to pregnancy, or in an individual subject to migraine.* It is too much the custom, I think, to regard convulsions in infancy as harmless, and not prone to recurrence. In a paper which I read several years ago,[1] I called attention to the fact that a large proportion of the cases of epilepsy in youths or adults, would be found upon careful inquiry to have had a convulsion in early life, that had usually been attributed to dentition or intestinal or febrile complaints; and of such early convulsions it may be very difficult to obtain a history unless the parents or some other near relatives are interrogated. The convulsions occurring in nephritis, or in certain women during pregnancy, are too well known to need more than a bare reference. Again, it is a curious fact, to which I have referred in the paper just mentioned, that migraine is interconvertible in certain individuals with epilepsy, so that most individuals who have a personal or hereditary history of migraine will be found upon minute and patient interrogation to have had a loss of consciousness or epileptic-like convulsion at some period of their life. If, however, pregnancy, migraine, nephritis, trauma, and preceding infantile convulsions, are excluded, a convulsion in an adult should give rise to grave suspicions of intracranial syphilis.

5. *Symptoms indicative of a lesion at the base of the brain.* Syphilis is especially apt to hug the base of the brain, and more especially that anterior portion of

[1] The Treatment of Epilepsy, N. Y. Med. Journal, June 28 and July 5, 1884.

it which forms the hexagon wherein lie the olfactory, the optic, the motor oculi, and the fourth pair of nerves, as well as the crura cerebri, and lesions of which impair the functions of these cranial nerves on one side of the body, and induce disturbances of motion and sensation upon the opposite side, giving rise to the so-called "crossed paralysis." Of course, tuberculosis has a predilection for the same site, but the history of the patient and the presence of pulmonary symptoms make easy a diagnosis of this affection. It is true also that tumors of non-specific origin may be found in the same location, but usually they are not so diffuse as a syphilitic infiltration, and usually also the specific lesions of this part of the brain are accompanied or have been preceded by a characteristic cephalalgia.

6. *A comatose condition extending over days or weeks, not traumatic, meningitic, diabetic, nephritic, or from opioid fever.* It is not always easy to exclude the coma of meningitis, especially in the early stage before the characteristic symptom of retraction of the head has made its appearance, although the temperature curve may be of great assistance. In my experience, this retraction of the head is of well-nigh infallible importance. Fränkel, however, has reported a rare and curious case, from the wards of the Charité Hospital in Berlin, in which this retraction of the head was found (post-mortem) to be due to a lesion in the middle portion of the ascending frontal convolution, just where the centre for the muscles of the neck has been located on *à priori* grounds by Wernicke. The coma of nephritis, it must also be borne in mind, is not always of the profound nature that is seen where the urine contains large amounts of albumen. It may be light, variable in its manifestations, simulating a profound hysterical condition. Nor will it do to exclude nephritis by a mere cursory examination of one specimen of the urine for albumen. Several specimens should be obtained. Best one at morn, midday, and evening, and the amount of urea should be estimated, casts, blood-corpuscles, and pus should be carefully searched for, and albumen should be sought for by the finer modern methods, rather than by the old and rough test by heat and nitric acid. I have more than once been called into consultation regarding conditions of coma, and I have been informed that nothing had been found in the urine to indicate nephritis, and yet the autopsy has disclosed advanced disease of the kidney. Diabetes can, of course, be easily ascertained. Some anomalous cases of typhoid fever are apt to mislead one at the start, although the progress of the disease almost invariably makes the diagnosis very certain.

7. *Tabes dorsalis*, and

8. *General paresis.*

It is not of much practical importance to ascertain the presence or not of a specific infection in these two grave maladies, because, so far as I have seen, the syphilitic causation has for them only this significance, that they will do rather better upon anti-specific treatment than the non-syphilitic cases; the course of the disease, however, is not materially altered.

9. *Spinal lesions in a subject who has had intra-cranial syphilis.* These spinal infections always require unusually large doses of the anti-specific remedy.

This quasi-periodical cephalalgia, this hemiplegia under forty years of age, this cephalalgia ceasing upon the supervention of hemiplegia, these convulsions in the adult, these lesions at the base of the brain, these comatose conditions may be present singly or in varied grouping, and singly or in groups they should always give rise to a strong suspicion of antecedent specific infection.

We have seen how difficult it may be to obtain the precise history of the initial lesion in such cases. The question at once arises as to what significance may attach to the success or non-success of anti-specific treatment. There can be no question that the profession are illogical in attaching the importance that they usually do to the results of such anti-specific treatment, because mercury and the iodides are efficacious in many affections that have no specific etiology. All the same, however, I cannot disabuse my mind of the fast-rooted impression that a disease which disappears rapidly and completely under anti-specific treatment, and which has not been affected by other forms of medication, is of specific origin.

The *prognosis* is dependent upon the question as to whether the lesions are destructive or non-destructive, and in many cases it is treatment alone that can determine this point. In general terms it may be said that syphilis of the nervous system is of good prognosis except where it has set up actual organic disease, except where it has excited in the normal tissue the formation of some other structure that is foreign to the particular texture. The infiltrations of the nervous tissues themselves, the gummata, the arterial lesions, are by themselves remarkably harmless. It is singular to see, as we often do, how much and how long the nervous structure will present evidences of syphilitic disease and yet recover entirely under adroit and vigorous treatment. Buzzard tells of an artery that had been almost occluded, being tested by the sphygmograph and yet was freed by proper treatment. To speak more precisely, it may be said that the symptoms of good omen are:

Nervous syphilis in its early stage: lesions at the base of the brain; spinal lesions without preceding intracranial specific disease; peripheral lesions.

Of uncertain omen are:

Long standing nervous syphilis;

Syphilitic insanities;

Spinal lesions with preceding intracranial specific disease;

Convulsions;

Comatose conditions;

Hemiplegia.

Of bad omen are:

Tabes dorsalis;

General paresis;

Nervous syphilis in persons whose general health is bad;

Relapses in spite of anti-specific treatment;

Nervous syphilis in persons who bear the iodides badly.

I have very pronounced ideas in regard to *treat-*

ment. I know of no reason for dogmatism except considerable experience, and that is my excuse for my dogmatism. I have no faith whatsoever in mercury, and I have discontinued its use for some time past. Again and again have I seen cases go halting along in the most uncertain manner, under mercurial treatment, and yet have the symptoms been smoothly, gradually, and certainly removed by the iodides. In several cases, too, I have known of death, although the most careful mercurial treatment had been pursued in enormous doses, and these cases have been precisely similar, as far as anyone is able to judge of one case by another in the practice of medicine, to others that I have been accustomed to regard as of favorable prognosis under the treatment by the iodides. I am quite prepared to say, that unless the iodides with their proper adjuvants—of which I shall speak in a moment—can cure a case of nervous syphilis, it cannot be cured at all. But the dose of the iodides which are administered by the Germans and French will often be entirely inadequate. I give the iodides until the symptoms yield, or until iodism is produced. I make use of the saturated solution of the iodide of potash, each drop of which contains almost a grain of the salt. I commence with twenty drops three times a day, and increase it each day by two or three drops at each dose, and keep increasing until the symptoms yield or iodism is produced. Should iodism ensue before the symptoms yield, I pursue one of two methods. I first increase the dose of the iodide by about one-third, and rapidly increase each succeeding day. Singular to say, in some cases this increased dosage will cause the iodism to disappear, and the larger doses will be borne very well. Should, however, these larger doses still more increase the iodism, I decrease to one-half of the dose at which the iodism had begun, and continue this decreased dose until the iodism diminishes or disappears, when I again rapidly increase the dose, and am usually able to go on without further trouble. In some few individuals, however, no amount of care will cause more than a certain amount of the iodide to be borne, and such cases, as I have said, are usually of unfavorable prognosis. In some cases, too—fortunately they are rare—even small doses of the iodide will produce a cardiac disturbance that prohibits its administration. But this last fact should not be confounded with the phenomenon that the profession generally does not seem to be cognizant of, namely, that small doses of the iodide, five or ten grains, will usually produce more iodism than the larger doses. I am perfectly well aware that the medical chemist will object that these large doses of the iodide pass through the body and are quickly excreted by the urine; but I am equally well aware, in the face of this fact, that these large doses of the iodide will cause symptoms to yield that cannot be made to yield by lesser doses. I have given as much as eight hundred grains of the iodide of potash in the twenty-four hours, and have seen symptoms disappear with these enormous doses that would not yield to minor ones. I administer the iodide after meals, and either in a full tumbler of ice-water, or in a glass of Vichy, or in a glass of a Bohemian spring water, the Giesshübler. I prefer the Giesshübler to the Vichy, although it is more expensive, because it is much more pleasant to the taste, and agrees much better with the average stomach. Moreover, the Vichy water which is put up in siphons in this country is artificial, by no means equal in its effects to the natural water, and the natural water, either of this country or of Europe, does not keep as well in bottles as does the somewhat similar water of the Bohemian spring.

But he who expects to cure his patient with the iodides alone, unless the case be so grave as to call for immediate relief, will be disappointed. The human organism must be put in the best possible condition. A generous diet should be employed. Freedom from care and worry, where possible, should be enjoined, and all strenuous exertion of body or mind avoided. And let me say here that in many broken-down individuals the most satisfactory results may be obtained from a conjunction of the iodides with the brilliant treatment that has been made known by Dr. Weir Mitchell, under the name of "Fat and Blood making"—a therapeutical procedure that, in my humble opinion, will rank in coming years with the surgical revolution inaugurated by Lister. When the acute symptoms have been brought under control, travel, especially an ocean voyage, will often work wonders. In every case that tends to chronicity staple tonics and alteratives should be used.

I have often asked myself, when a person can be considered to be cured of nervous syphilis; and I have never succeeded in answering the question to my own satisfaction. I know of no data by which we can guide ourselves. I have seen relapses occur years after the disappearance of every untoward symptom, and I have seen them even where a certain moderate treatment by the iodides had been maintained. I usually impress this uncertainty upon my patients, warn them to be on the lookout for future symptoms, and apprise whoever may be their attending physician of their possible significance, and I enjoin them to keep up moderate doses of the iodide for years. This last precaution I observe the more readily because I have but seldom seen any ill-effects from the continued administration of the iodides, to which patients usually become accustomed as they do to common salt. Occasionally it may happen that an obstinate pharyngeal or post-nasal trouble may be induced, or some unsightly cutaneous eruption, but, as a rule, these are controllable, and in any event they are far preferable to the possibilities of nervous syphilis.

SURGICAL PUNCTURE OF THE HEART. A WARNING.

By T. WESLEY MILLS, M.A., M.D.,
Professor of Physiology, McGill University, Montreal.

There appeared in The Medical News of June 4th, a paper entitled, "An Experimental Study of the Effects of Puncture of the Heart in Cases of Chloroform Narcosis," the author of which seems to be unaware of certain phenomena that result from puncture and other forms of cardiac stimulation, to which it is proposed briefly to direct attention, on account of the relation they have to the practical bearings of the subject.

That a heart that has recently ceased to beat can often be restarted by needle puncture, etc., has been known for physiological ages, and it needed no further lengthened series of experiments to demonstrate it. In 1884, Professor Kronecker, then of Berlin, ascertained, at first accidentally, that a needle thrust into the heart of a dog may arrest the ordinary ventricular beat, and substitute for it a "fibrillar" action, a sort of incoördinated movement of the muscular fibres, quite ineffective in expelling any blood from the organ. The auricles continue to beat as usual, and while they remain amenable to the action of the vagus nerve, the ventricles pass wholly beyond its control.

Professor Kronecker made many experiments, and gave several demonstrations, at some of which I had an opportunity to assist, as I then was enjoying the hospitality of the Berlin Physiological Institute. An account of these researches was published in the proceedings of the Berlin Medical Society, I believe. It was found that the vulnerable area was near the line of the left coronary artery, therefore near or in the septum of the ventricles, at about one-third of the distance from the base of the heart. Professor Kronecker assumed the existence of a nervous "coördinating centre," which, however, he had not at that time demonstrated anatomically.

This phenomenon I demonstrated in the Physiological Laboratory of McGill University, before the physiologists attending the meeting of the British Association for the Advancement of Science, in Montreal, in 1884, when the causation of this most curious behavior of the heart gave rise to an interesting discussion.

In the investigations on the hearts of the cold-blooded animals which I have been carrying on during the past three years, a good many opportunities have been afforded me of studying the phenomenon as it is manifested in them. It can be readily induced in the sea-turtle by electrical stimulation of the ventricles. In one case it seemed to have been originated in the terrapin by the entrance of sodium carbonate into the heart during a blood-pressure experiment.

From the fact that one may make many punctures as near to the suspected area as can be guessed without inducing fibrillar action, while after the heart has been long experimented on in some other way, or its vitality otherwise lowered, merely seizing it with the hand may originate the action in question, it has occurred to me that it is a result of stimulation of the muscle under peculiar conditions; in fact, that it is not of nervous, but of muscular origin.

That it is so in the turtle, very numerous observations leave me no room to doubt. It can be induced in dogs, rabbits, and the chelonians, by electrical stimulation as well as by puncture, manipulation of the heart, etc. But there is this most important difference in these animals, that while they all, except the dog, recover from this aberrant behavior of the heart, in this animal it is *invariably fatal*, the creature being as surely asphyxiated as if his heart had ceased to contract.

Whether puncture must be confined to the very circumscribed area referred to above, to cause the fibrillar contraction, I am unable, from personal observation, to say; but that there is no such limitation in the turtles I have again and again proved. The phenomenon in the dog lasts from seven to ten minutes when the heart is arrested beyond the power of recovery. There is reason to believe that the heart of man would behave similarly to that of the dog. It is easy to understand why, if the area that is vulnerable is limited, or if the effect is dependent on the condition of the cardiac muscle, scores of punctures might be made without a fatal result. Indeed, Prof. Kronecker stated that his discovery explained why slight wounds of the heart had in some cases proved fatal, while much more serious ones, from the surgical point of view, had been comparatively harmless. This physiologist also thought physicians were, in the light of these facts, no longer justified in using electricity over the heart to recover from chloroform narcosis, etc.

I have no intention of entering upon a general criticism of the paper which has called forth these remarks, but when the author of that paper transfers his conclusions from dogs to men (a process not perhaps physiologically very objectionable in itself in such a case), and seriously proposes needle-puncture *as a remedy*, knowing the facts referred to above, it is impossible that I should remain silent, and not sound a warning against such a *possibly* dangerous procedure. The insertion of a needle into the heart might excite the quiescent organ to action, while again it might cause a feebly beating heart, that would perhaps recover if given a chance, to become hopelessly incoördinated.

HOSPITAL NOTES.

TREATMENT OF CHOLERA INFANTUM IN THE NEW YORK HOSPITALS.

Bellevue Hospital.

Dr. A. Jacobi treats the cases which come into his ward, as follows:

Internal Medication.—*Empty the stomach and bowels* of fermenting masses. The castor oil of the lay

public answers well. A dose of calomel (grs. j–vj) answers better, because it acts as an anti-fermentative, beside being a purgative.

Neutralize acids (fat acids) in the stomach. Carbonate or phosphate of calcium, grs. j–ij, every one to two hours, acts as an adjuvant to other treatment. Bismuth also answers this indication, besides being an anti-fermentative. Dose, grs. ss–ij every one to two hours. May (must) be combined with opium, Dover's powder, grs. $\frac{1}{10}$–$\frac{1}{5}$–$\frac{1}{3}$, every one, two, to four hours. No salts of magnesium or sodium, because they add to the diarrhœa in these acute cases. Avoid syrups to correct the taste of medicines. They will turn sour. Prefer glycerine.

Anti-fermentatives.[1]—Calomel, bismuth, alcohol, creasote, salicylate of sodium, and resorcin have been recommended for their anti-fermentative effect. Of the two latter I prefer resorcin, iv–x grains *a day*, in solutions (suspensions), or as a constituent of powders (with bismuth, chalk, opium).

Sedative.—Opium depresses hyperæsthesia, hyperperistalsis, and hypersecretion. Dover's powder (gr. $\frac{1}{10}$ to $\frac{1}{3}$ every two to three hours) acts very well, though some writers object to it, and is indispensable. Does well with bismuth, and prepared chalk, with or without resorcin.

Astringents.—In acute cases, and when the stomach participates in the process, lead, tannin, gallic acid, alum, etc., are badly borne. In chronic protracted cases they will find their indication. Nitrate of silver does better in many acute cases, gr. $\frac{1}{20}$th to $\frac{1}{10}$th in 2 drachms of distilled water (dark bottle) every two hours. Creasote water in chronic cases.

Stimulants.—Alcohol may be admixed to food. Bad brandy or whiskey contains fusel oil, which is a paralyzing agent. Whiskey is therefore preferable with us, because it can be obtained in greater purity for less money. (See under "Food.") Never give it raw. Camphor is better borne than ammonia. It is easily taken when simply rubbed off with glycerine suspended in mucilage (gr. $\frac{1}{4}$—ij every one to two hours). The strongest nerve stimulant of all is *Siberian* musk. Give in *urgent* cases of collapse gr. i–ij every fifteen or thirty minutes (best suspended in mucilage) until six or twelve grains have been taken. A very good stimulant in collapse is the injection into the bowels through a long flexible tube (catheter No. 12) of hot water with some alcohol, and one or a few drops of tinct. op.

External Applications and Hygiene.—In acute cases with high temperature applications of water of 60°–70° to abdomen. Where much pain and with anæmic children, warm applications do better. Frequent injections of water of 100° F. answer well in most cases, not only in rectal catarrh. In collapse or great debility, the water ought to be from 105° to 112° F., and contain some alcohol and opium. Part of this water will be absorbed, fill the bloodvessels, and may prevent intracranial and other thromboses. The addition of gum-Arabic to the injection, or the use of glutinous decoctions (flax-seed) instead of water is quite satisfactory. Open doors and windows in hot weather. Select the coolest place in the neighborhood for the patient, day and night. Night air is better than no air. Country air, sea air, better than city air, particularly at some altitude. When the body is warm and the weather hot, wash the body with cool water, or alcohol and water (1 : 5) frequently. Cold feet must be warmed artificially.

Food.—No raw milk, no boiled milk, no milk admixture at all, in bad cases. In vomiting and severe diarrhœa, *total abstinence* for from one to six hours. Afterward teaspoon doses of a mucilaginous or farinaceous decoction. Regular food : 5 ounces of barley-water, 1–2 drachms of brandy or whiskey, the white of 1 egg, salt and sugar, teaspoonful every five or fifteen minutes, according to age and case. May be mixed with mutton-broth, which, with white of egg, etc., is better than beef soup or beef-tea in convalescence. Abstinence better for vomiting than ice; the latter may quiet the stomach, feel pleasant, but stimulates peristalsis. Avoid beef-tea. If it be given in convalescence, mix it with barley-water.

Toward the end of the disease, or when the discharges are many and copious, and inspissation of blood, and thromboses (hydro-encephaloid) threatening, the common sense of the practitioner will introduce liquid into the circulation as best he can. No written rule ever supplies or substitutes brains.

New York Infant Asylum.

Dr. L. Emmett Holt holds that as pure air and proper feeding are the most important things in prophylaxis, so they are the most important in the treatment of this disease. Sick or well, there is no food for a baby that compares with good breast milk. If this is being used, or can be obtained, the quantity only needs to be regulated. Not more than half the child's allowance when well should be given, and if the stomach is very irritable, all food should be withheld for half a day or a day, giving nothing but toast-water or thin whey to allay thirst. If a child has been weaned, or good breast milk cannot be obtained, cows' milk had best not be trusted, as it is so easily changed in hot weather, especially in cities and among the poor. In the country, where fresh milk can be obtained twice a day, it may not hold; but in the city, children certainly do better when milk is withheld, and other articles not so prone to fermentation are given. Chicken, beef, and mutton broths, expressed juice of roast beef or steak, wine-whey, white of egg shaken up with water, rice-water, barley-water, or the malted foods, koumyss, and in some cases raw scraped beef, are articles with which we may replace milk.

The first indication in every case, except true choleriform diarrhœa, is to clear out the bowels as completely as possible, by a good dose of castor-oil, or by one or two grains of calomel in the form of tablet triturates. This will be sufficient to cure a large number of the

[1] The practice of giving anti-fermentatives has preceded the theory for centuries. Still the theory is not quite so recent as a few modern journal articles appear to believe. In "Treatment of Infant Diarrhœa and Dysentery," by A. Jacobi, M.D., in *Amer. Journ. Obst.*, etc., July, 1879, there are the following remarks:

"A further indication is to destroy ferments. For that purpose most metallic preparations will do fair service. One of these is calomel . . . as to its effect as an anti-fermentative there can be no doubt. . . . Possibly, it acts by a portion of the drug being changed slowly into the bichloride of mercury."

"Alcohol certainly arrests fermentation."

"Sometimes, particularly when the stomach can be relied on, the salicylate of sodium may be added to the internal treatment. . . . The salicylic acid may prove beneficial, both by its antifebrile and disinfectant action."

milder cases, if taken early, provided the feeding rules laid down are carefully followed. In more severe cases, and in those of longer standing, a simple clearing out produces only temporary improvement; further measures must be taken to restore healthy action of the alimentary tract and stop decomposition. Salicylate of sodium, in grains j–ij doses, every two hours, or naphthalin in double the amount, we have found the most useful.

High temperature should be reduced by baths or cold sponging. It should not be forgotten that this may come from septic absorption from the bowels; if the temperature has risen coincidently with a great reduction in the number of discharges, a brisk cathartic will prove the most efficient antipyretic.

Cerebral symptoms may likewise be toxic, and, if so, should be treated in the same manner.

The object of treatment is not simply to arrest the discharges, but to restore their healthy character. Hence, opiates are not admissible at the outset, and never during the course of the disease when the discharges are foul and offensive. The retention in the intestinal canal of such matters, loaded with bacteria, can only result in harm.

Last summer, in this Asylum, a trial was made of the method of irrigation of the bowels with simple water or weak astringent solutions, in twenty-one cases. Only eleven were cured by this treatment alone. Although the results were not so gratifying as was anticipated from the accounts published in Germany, still some very bad cases did surprisingly well under it. It is certainly deserving of a more extended trial, as a valuable addition to our therapeutics.

True choleriform diarrhœa was treated in a few cases by hypodermatics of morphia and atropia; one or two yielded quite promptly; others, no more severe apparently, were uninfluenced by it.

The German Dispensary.

Dr. Augustus Caillé varies the treatment with the period at which the child comes under observation. Inasmuch as a simple dyspeptic diarrhœa may develop into the most violent choleraic diarrhœa through the agency of high temperature and improper feeding, it will be well to consider briefly the prophylaxis of cholera infantum—*i. e.*, the treatment of gastric catarrh, with tendency to diarrhœa. The diet of the sick child must be at once restricted. Food should be withheld for a period of from six to twelve hours, and water given *ad libitum*, also oatmeal, barley, toast-water, and lime-water. Nursing babies can be deprived of the breast for the same length of time.

The bowels should be evacuated by means of castor oil, magnesia cum rheo, or calomel gr. ½, sugar gr. v, pro dosi, given every hour until five are taken. It is best to place the powder dry upon the tongue. If the tongue remains coated twenty-four hours after the administration of calomel, etc, dilute hydrochloric acid, with or without pepsin is indicated.

R.—Acid. muriat. dil. . . . gtt. xl.
Aquæ . . . . ℥j ss.
Pepsini pur. . . . . ℥ss.
Syrupi simp. . . . . ℥ij.—M.
Sig.—Teaspoonful every hour.

Or,

R.—Acid. muriat. dil. . . . ℥ss.
Aquæ . . . . ℥xiv.
Tincturæ opii . . . . gtt. ij.
Syrupi simp. . . . . ℥ij.—M.
Sig.—Teaspoonful every two hours.

In acid dyspepsia, alkalies (mist. cretæ) are indicated.

In order to save time and prevent misunderstanding, Dr. Caillé has found it a good plan to have a diet-card printed, which he presents to the parents, telling them to give to the sick child the articles of diet which are not crossed out. The articles enumerated on the cards are as follows:

Barley-water, oatmeal-water, white of egg in water, gum Arabic in water, lime-water, whiskey in water, bread crust boiled in water and allowed to cool, milk with any of the above waters, meat broth with any of the above waters, cold tea.

The acute attack (cholera infantum) calls for the following treatment:

1. Antifermentative (antiseptic) measures.
2. Rest for the intestinal tract.
3. Stimulation and prevention of collapse.

If a child is seen early, before collapse has set in, it should be kept as quiet as possible, and no food given for six to ten hours, on account of irritability of stomach. Pounded ice, with or without whiskey, cold tea, ice tied in a rag to be held in the mouth, are advisable; also, lime-water, toast-water, rice-water.

To meet indications 1 and 2 he relies upon the following drugs:

R.—Bismuth. subcarb. . . . ℥j.
Aquæ cinnam. . . . ℥ij.
Tinct. opii . . . . gtts. ij.—M.
Sig.—Teaspoonful every one to two hours.

Or,

R.—Sodii benzoatis . . . ℥j.
Aquæ . . . . ℥xiv.
Syrupi . . . . ℥ij.—M
Sig.—Teaspoonful every two hours.

Or,

R.—Acid. carbol. pur. . . . gtt. ij ad vj.
Mucilaginis . . . . ℥ij.—M.
Sig.—Teaspoonful every two hours.

Or,

R.—Argenti nitratis . . . gr. ij.
Aquæ destil. . . . ℥ij.—M.
Sig.—Teaspoonful every two hours.

Or,

R.—Resorcin . . . . gr. ij.
Aquæ cinnamomi . . . ℥ij.
Tinct. opii. . . . gr. ij.
Sig.—Teaspoonful every two hours.

He avoids the addition of syrup to a mixture, if possible, and omits the opium if the patient apparently has little or no pain.

When children are very restless, and show by their actions that they suffer pain, he does not hesitate to give

small doses of opium, one, two, or three drops in a two-ounce mixture.

A towel wrung out of cold water and secured over the abdomen, appears to relieve pain; and a warm mustard bath stimulates in impending collapse.

For obstinate vomiting he frequently gives:

R.—Tr. iodin. . . . . gtt. xv.
Aquæ menthæ . . . . ℥j.
S.—15 ℳ every hour.

A change of air is of the utmost importance. Children taken from a hot tenement to the seashore, or any cool, shady place, improve perceptibly in a short time, if not too far collapsed.

Large enemata of tepid water, with or without the addition of some antiseptic drug (acid. salicyl.), should be tried in obstinate cases, but in dispensary practice this method cannot well be carried out.

Stimulation must not be delayed until symptoms of collapse are marked. Young children with high temperature, cold and clammy feet and hands, and a pulse too rapid to be counted, are frequently stimulated in vain. The best stimulants in his experience are:

R.—Camphoræ . . . . gr. ¼.
Sacchar. . . . . gr. vj.
Pro dosi, one every three hours.

R.—Camphoræ . . . . gr. ¼.
Pulv. Doveri . . . . gr. $\frac{1}{10}$.
Pro dosi, one every two hours.

R.—Camphoræ . . . . gr. j.
Bismuthi . . . . gr. vj.
Pro dosi, one every two hours.

If the children vomit the drug, it will be necessary to give camphor in ether, or camphor, caffeine, and ether hypodermatically.

In dispensary practice children cannot be seen oftener than once every other day, or every day at the utmost; it is, therefore, a good plan to prescribe antifermentative medicine and camphor powders at one consultation, and direct the parent to give the powder after the medicine has been taken.

During the period of reconvalescence, astringents are indicated to combat the intestinal catarrh, such as tannic acid, acetate of lead, with or without opium. To guard against relapse, it is of the utmost importance to select the proper food for children deprived of the breast. In the majority of cases milk and oatmeal or barley gruel, in different proportions, according to age, with a pinch of salt, some sugar, and, if necessary, lime-water, will be the proper food for a child up to twelve months. This food has been repeatedly recommended by Prof. A. Jacobi for the past twenty-five years. If it fails, others should be tried. Dr. Caillé has had good results from the employment of the so-called "peptogenic milk powder," and one or two other preparations recently introduced.

MEDICAL PROGRESS.

A NEW AND IMPERVIOUS SURGICAL DRESSING.—Photoxylin, a substance in use amongst photographers, was recommended some time ago by DR. KRYSINSKI as a suitable material for mounting microscopic specimens, and more recently still it has been utilized by Professor Wahl, of St. Petersburg, as a substitute for collodion in surgical practice. A five per cent. solution in equal parts of alcohol and ether he finds preferable to collodion, as it adheres more firmly to the skin, not being so easily rubbed off in washing. It is absolutely impervious to liquids, and exerts a perfectly even compression on the tissues. In out-patient practice Prof. Wahl finds that, after small operations such as the extirpation of glands, the application of photoxylin solution enables him to dispense entirely with voluminous antiseptic dressings; also in plastic operations on the face, and in operations in the neighborhood of the male genital organs, such as those for the radical cure of hernia and castration, where it is very difficult to prevent the urine soaking through antiseptic dressings. Prof. Wahl, after carefully arresting all hemorrhage, closes the wound with sutures and gelatine plaster, and then covers the whole with a thin layer of wool soaked in a solution of photoxylin. This, it is stated, will remain eight or ten days, entirely resisting all the effects of moisture. Even in laparotomy, extensive dressings may, he believes, be dispensed with by painting a solution of photoxylin over the wound with a brush, or by the application of a layer of cotton-wool soaked in the same liquid. —*Lancet*, June 18, 1887.

A RARE COMPLICATION OF PLACENTA PRÆVIA.—DR. GEORGE LOGAN reports, in the *Lancet* of May 21, 1887, a case in which, in addition to placenta prævia, the placenta was adherent in the following remarkable manner: "After turning, the child was easily delivered, but it was dead. It now became evident why the placenta could not be extracted; it was intimately adherent to the head of the child. As nearly as could be calculated, the surface of attachment measured in diameter about two inches and a half, and the situation of its centre was a point a little below the posterior fontanelle. The neck of the child was very short, the head having the appearance of being attached to the trunk, without neck at all. The forehead receded very much, so that the supra-orbital ridges became very prominent, as were also the eyes; the bridge of the nose extended upward beyond the eyes, and separated them. The cord was quite natural, both at its origin and insertion, and in every other respect the child, which was a male, was well developed. The mother made a good recovery."

THE DISINFECTION OF DWELLINGS AND THEIR CONTENTS.—GUTTMANN and MERKE, at a recent meeting of the German Society for Hygiene, reported their experiments with solution of corrosive sublimate, one per cent., in spray, in the disinfection of carpets and hangings. It was found that colored materials and walls were not injured by the spray that was used, which made the surfaces quite wet. Of 200 carpets disinfected none were injured. Sublimate was found upon the walls twenty-seven days after the disinfection; and to hasten its removal a one per cent. solution of sodium carbonate was used, which formed an insoluble mercuric oxychloride, which could be easily removed from the walls by sponging and drying. Material saturated with cultures of anthrax and placed among the materials disinfected, showed a destruction of half the germs;

it is probable that improvements in the manipulation will increase the efficiency of the process. With ordinary care, those who made the disinfection were uninjured by the sublimate.—*Wiener medizinische Presse*, May 15, 1887.

Treatment of Flatulent Dyspepsia.—Huchard recommends the following formulæ:

Salicylate of bismuth	2 parts.
Calcined magnesia	2 "
Powdered willow charcoal	3 "
Oil of anise	1 part.

Of this powder a small teaspoonful may be taken an hour or a half hour before a meal. When gastralgia is added to flatulent dyspepsia, he recommends the following:

Syrup of peppermint	250 parts.
Hydrochloric acid	1 part.
Hydrochlorate of cocaine	$\frac{1}{50}$ "

of which a small glass (such as those in which liqueurs are served) may be taken after a meal.—*Revue Générale de Clinique et de Thérapeutique*, May 19, 1887.

Intubation of the Larynx at the Boston City Hospital.—Dr. Prescott, house surgeon, reports the following method of treatment by intubation at the above mentioned hospital:

The treatment has been the same as in tracheotomy, namely: light steam, stimulants, poultice over chest; Dobell's solution[1] as a throat spray. A solution of corrosive sublimate (1 to 15,000) was applied to nasal mucous membrane when there was any nasal discharge. Occasionally small doses of the bichloride of mercury were given. Tincture of digitalis, in small doses, was also given when the urine was scanty, and pepsin to assist digestion, when necessary. At first nourishment was given in enemata, but it was soon found that all the nourishment needed could be given by mouth, without difficulty. Semi-solids cause the least trouble. The first and last "swallows" are the ones that cause the coughing which is always set up, and so it is best to let the child take a mug of milk and drink it rapidly.

The advantages of intubation, as compared with tracheotomy are: 1. There is no wound, and therefore it will be allowed where tracheotomy might not be. 2. There is not added another source by means of which infection may take place. 3. It can be done more quickly. 4. It is less troublesome both in its performance and its after-care. 5. There is not as much discharge. 6. The shock is not as great. 7. No anæsthetic is needed.

The great disadvantage is that the parts below the larynx cannot be kept as free from mucus and membrane as in tracheotomy. Although the fact that intubation can be done more quickly has been put as an advantage, I do not wish to imply that it is a simple procedure. It is not easy, and should be done with a great deal of care and very little force. The statement has been made that it is easier to put a tube into the larynx than into the œsophagus; the experience at the hospital does not bear out the statement.

The method of inserting the tube, as done at the hospital, is as follows: The tube with the silk attached having been put on the obturator, the child should be held upright by an assistant, sitting in a chair facing the operator, with its head held firmly and a little forward. The gag is introduced on the right side and kept as far back as possible. The operator then introduces his left forefinger into the mouth and passes it downward and backward until he feels the epiglottis; he now passes the tube along the palmar surface of his left forefinger (keeping in the median line) until the tube reaches the epiglottis, when, by an upward movement of the right hand, he can easily put it in place. The left forefinger having been placed on the tube the obturator is withdrawn. After a few minutes, the breathing being quiet and the tube having again been felt in position, the silk suture may be removed, and the patient put to bed.

The number of cases is too small to be of much service in forming an opinion as to the relative value of intubation and tracheotomy from the standpoint of percentage of recoveries; for if the statistics of tracheotomy at this hospital are examined, the percentage of recoveries in any given six months will be found to vary from ten per cent. to thirty-five and even forty per cent.—*Boston Medical and Surgical Journal*, June 2, 1887.

An Application for Burns of the Second and Third Degrees.—

R.—Terræ albæ,	
Ol. olivæ	aā ℥ 7½.
Plumbi subacetat.	gr. ½.
Iodoform.	℥ 2 to 4.

Mix: Apply with a spatula, and cover with gutta-percha tissue or cotton, and a muslin bandage.—*Journal de Médecine*, May 16, 1887.

Transperitoneal Nephrectomy.—Terrier reported, at a recent meeting of the French Society of Surgery, two cases of nephrectomy in which he sutured both layers of the peritoneum to the anterior abdominal incision; the pocket formed by the removal of the kidney was thus drained anteriorly. He prefers the abdominal incision in large tumors projecting anteriorly.—*Gazette Hebdomadaire*, No. 12.

Use of Cocaine.—At a recent meeting of the Society of Therapeutics of Paris, Dujardin-Beaumetz reported his use of cocaine in the throat to render more easy gastric lavage. He had given it internally, in gastric disorders, in a solution of 1 to 600, two teaspoonfuls every fifteen minutes, to allay pain and vomiting. He had also given four injections, of half a hypodermatic syringe each, of a solution of 1 to 50, in the vicinity of the anus, and had thus obtained anæsthesia sufficient to dilate forcibly the sphincter without pain; a pledget of cotton saturated in the same solution may be placed in the bowel. In pleurotomy similar injections may be made at each extremity of a proposed incision.

All such injections should be given with the patient in a horizontal posture, to avoid syncope.

[1] Dobell's solution:

R.—Carbolic acid	℥ lxx.
Borax	ʒ j.
Boracic acid	ʒ j.
Glycerine	ʒ iss.
Water	ad Oiv.

He thought that as much as eight grains of cocaine could be given internally in twenty-four hours.—*Gazette Hebdomadaire*, May 6, 1887.

MIKULICZ'S METHOD OF DRAINING THE PERITONEAL CAVITY.—DR. FENGER, of Chicago, describes his use of the above method in cases reported in the *Journal of the American Medical Association*, of May 21, 1887:

About a year ago Mikulicz, of Cracow, proposed the following method of drainage, not only for retro-peritoneal cysts, which can be excluded from the general peritoneal cavity, by uniting them to the abdominal wound, but also for drainage in the peritoneal cavity itself. He takes a small piece of iodoform gauze, stitches a silk thread to the centre of it, and folds it up in the form of a pouch, the silk thread being inside, that the pouch may be drawn up from the bottom by it. The pouch is now pushed down to the bottom of the cavity, and if nooks and corners exist, it is pushed out so as to fill them completely. The inside of the pouch is packed with iodoform gauze, as much as is necessary to fill up these spaces completely. This is the advantage claimed by Mikulicz for his method of drainage as compared with the use of glass or rubber drainage. Besides the disinfectant properties of the iodoform gauze applied to the entire wall of such a cyst, Mikulicz states, as one of the advantages of his method, that, by the capillary attraction of the gauze, everything is brought out—fluids which a glass or rubber drain could not bring out. We must remember that when we drain the peritoneal cavity with a glass drain down between the intestines, or in the cavity of the cyst, we cannot always expect to get surrounding organs in so close contact with the drain as to drive out the fluid.

Further, there is this to consider: that a glass drain put down in the free peritoneal cavity has no tendency to bring out the fluid accumulated at the bottom; the intestines, filled with air, will simply swim in the fluid, and there is no pressure from without that will bring this fluid out of the glass drain, while the capillarity of the gauze is likely to help in that direction. I have had this remain in all these cases for about two weeks. As soon as the discharge ceases I commence first to pull out the loose gauze inside the sac. If a space is left after this has been pulled out, I press in at that dressing a little more gauze. This is gradually removed, and the pouch itself is then pulled out by the thread gradually and finally. In all my cases it came out about the end of the second week.

THE TREATMENT OF PAIN ABOUT THE COCCYX.—MÉNIÈRE, in addition to the relief of constipation and the use of counter-irritants, advises the following, in suppository, per rectum:

Ol. theobrom.	℥ 20.
Ex. belladonn.	gr. ¼.
Ext. hyoscyami	gr. ½.
Iodoform	gr. ¼.

To be used before retiring.

In severe coccygalgia he recommends the following:

Ol. theobrom.	℥ 20.
Ext. valerian.	gr. 1½.
Chloral. hydrat.	gr. 1½.

To be made into a rectal suppository which may be replaced, if necessary, by an injection of forty minims of

Adipis	ʒ 5.
Ext. valerian.	℥ 15.
Ext. belladonn.	℥ 8.
Chloral. hydrat.	gr. 15.

—*Gazette de Gynécologie*, May 15, 1887.

THE PERSISTENCE OF TYPHOID BACILLI.—FRÄNKEL, of Berlin, observed an interesting case in which a patient who had typhoid fever, had relapses at intervals of six weeks and four months, after which a fluctuating abdominal tumor developed. Aspiration gave pus and typhoid bacilli, cultures of which were characteristic. The case was regarded as one of inflammation produced by the persistence of the typhoid bacillus which had multiplied, instead of attenuating after the disease had abated, as usually happens.—*Gazette Hebdomadaire*, May 20, 1887.

THE MODERN TREATMENT OF URETHRITIS.—DR. BREWER, in an article in the *Journal of Cutaneous and Genito-Urinary Diseases* for May, gives his results of treatment as follows:

In conclusion, I think it may be fairly stated:

1st. That in uncomplicated cases of acute gonorrhœal urethritis, treated by prolonged and frequent irrigation with bichloride of mercury, recovery may be expected within two weeks; that this period may be considerably shortened by the early inauguration of treatment, by absolute rest, and by the avoidance of stimulants; that it may be indefinitely prolonged by irregularity in treatment, by inordinate physical exertion, and by indulgence in alcoholic and venereal excesses.

2d. That the retrojection of a hot solution of bichloride possesses all the advantages of the former procedure, and in addition causes a more rapid subsidence of the inflammatory symptoms, a greater feeling of comfort to the patient, and is attended with less annoyance and trouble.

3d. That in cases of acute non-specific urethritis, the favorable influence of each of these methods is strikingly apparent.

4th. That in cases of chronic purulent urethritis, no agent produces such rapid and permanent improvement as irrigation, especially when combined with astringents and heat.

5th. That the percentage of complications occurring in cases treated by these methods is far below that observed when the ordinary methods are employed.

TREATMENT OF CHOREA.—DESCROIZILLES prescribes as follows:

R.—Zinci valerian.
Ext. hyoscyami,
Bismuth. subnitrat. . . ãã gr. 15.—M.
Divide in pill 30 in number.

Sig.—From 3 to 6 pills daily.—*Journal de Médecine de Paris*, May 23, 1887.

ALMÉN'S TEST FOR SUGAR.—Of all tests for sugar in urine, Fehling's is undoubtedly the most satisfactory. The only objection that can be urged against it is the difficulty of preserving it a sufficient length of time, so

that unless recently prepared it may lead to fallacious results, owing to the solutions having a tendency to throw down the suboxide of copper spontaneously when heated. This, of course, is a great disadvantage to practitioners, who may be seldom called upon to use the test, and are at a distance from manufacturing chemists from whom they may procure a fresh supply. To remedy this Professor Almén, of Upsala, has improved the old bismuth test for sugar, and has prepared a solution which has the advantage of keeping unchanged for years, and being at the same time an extremely delicate test for sugar in urine. It consists of a solution of bismuth subnitrate, with caustic soda and potassio-sodium tartrate. In testing for sugar, the albumen, if present, must be first removed by precipitation by heat and acid, and one part of the solution treated with ten of the urine, when if sugar is present the bismuth will be deposited in a metallic state. The test is sufficiently delicate to detect sugar in the proportion of only 0.05 per cent. This test, as we have already said, is chiefly valuable on account of its preservative qualities, keeping well on board ship and in hot climates, though we doubt if it will supersede the use of Fehling's solution, especially as the latter is now supplied in hermetically sealed capsules which preserve the test for a considerable time.—*Lancet*, May 14, 1887.

Treatment of Ozena by Animal Grafting.—In a research upon "Animal Grafting with the Skin of the Frog, in Losses of Cutaneous and Mucous Substance," undertaken along with Dr. Dubousquet-Laborderie, Baratoux publishes observations upon ozena, atrophic rhinitis with ulcerations, in which he obtained a complete cure by engrafting the skin of a frog over the ulcerated surfaces. He has thus treated eleven patients having ozena and ulcerative non-specific rhinitis. In all these subjects he employed ten to twenty grafts, of which more than half have succeeded, and all the patients have derived much benefit from the treatment. He has always succeeded in obtaining a smooth mucous membrane. He takes the frog's skin from the interdigital membrane, the nictitating membrane, the belly, the lateral parts, by scissors, and places upon the raw surface with forceps, or by a special pipette (by blowing through the free extremity).—*Journal of Laryngology*, May, 1887.

Testing Menthol Pencils.—Mylius recommends testing the genuineness of the so-called migraine pencils by the following characteristics: The pencils should be of a coarsely crystalline structure, translucent, and not chalky. When scraped in water, the pencil should make the impression as if it were composed of a hard salt, and should not present a fatty or waxy appearance. If a small portion of the pencil be put into a narrow tube, and the latter be heated in a bath of diluted sulphuric acid, the mass should melt at a temperature at or below 38° C. (pure menthol melts at 36° C.). The whole mass of the pencil should melt at once, not successive layers from time to time. All substances used for adulterating the mass possess a higher melting-point, except some very low melting paraffines. But the latter are left behind, if the pencils are dissolved in alcohol.—*Technics*, May 3, 1887.

Thallin in Gonorrhœa.—Kreis and Goll have tested the effect of thallin upon the gonococcus and have found cultures of the germ destroyed by the drug. The sulphate in watery solution was used.

Staphylococcus aureus and anthrax bacilli were not affected by thallin.

After the internal administration of thallin the urine is strongly acid, and such urine undergoes ammoniacal decomposition much less early than urine ordinarily.

Injections of tartrate of thallin, 1 per cent., were well borne by the patients, but were without result. Solutions of $1^1/_2$ or 2 per cent. were but slightly irritant but showed good results. Decided improvement, however, followed the use of solutions of 2 and $2^1/_2$ per cent. in strength, with but slight irritation accompanying it.

In chronic gonorrhœa thallin gave good results when used immediately after the passage of a sound in solutions $1–1^1/_2$ per cent. in strength.—*Centralblatt für Chirurgie*, May 7, 1887.

A Common Antidote.—A poison antidote table says that equal parts of calcined magnesia, powdered charcoal, and hydrated peroxide of iron, in a sufficient quantity of water, is a general antidote for poisoning, for use when the poison is not known. It is a perfectly harmless and simple preparation.—*Technics*, May 17, 1887.

Carminatives and the Absorption of Gas by the Intestines.—Some experiments which were performed several years ago by Drs. Lauder Brunton and Cash, with a view to determine how carminatives act in relieving flatulence, have just been published. The gases used in the experiments were atmospheric air, carbonic acid gas, hydrogen, marsh gas, coal gas, and sulphuretted hydrogen. With the exception of one experiment the oil of cloves was the only carminative used. In each experiment they first tested the gases alone, and then again after the administration of the carminative. They found that little or no absorption took place when atmospheric air, hydrogen, coal gas, or marsh gas was used, and the addition of the carminative did not seem to increase the absorption. It was only in the case of carbonic acid that the carminative seemed to aid in absorption, and this was due probably more to the effect on the movements of the intestine than to direct absorption of gas. The oil of cloves caused a marked increase in the secretion of the intestine—a fact which, perhaps, explains the advisability of combining carminatives with purgatives. In regard to sulphuretted hydrogen, it was found that its absorption proceeded so rapidly as to produce even fatal poisoning, but carminatives did not exert much influence in increasing the absorption.—*Practitioner*, May, 1887.

A Useful Powder for the Treatment of the Uric Acid Diathesis.—Druitt is quoted by the *Journal de Médecine de Paris* of May 22, 1887, as prescribing as follows:

R.—Borac. pulver. . . . gr. 15.
Sodii bicarbon. pulv.
Potass. nitrat. pulv. . . . āā gr. 8.
for each powder.

To be taken 3 times daily in abundant fluid.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE. . . . . $5.00.

SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

THE CROWN PRINCE'S CONDITION.

(*Special Cablegram.*)

WE are in receipt of the following cablegram from Dr. Morell Mackenzie.

LONDON, July 7.

"THE last operation upon the Crown Prince has succeeded completely, and no projecting portion of the growth remains. Professor Virchow reports that the excised piece shows, even more clearly than the previous ones, as a hard, composite, warty growth, out of a moderately irritated and thickened surface. The base shows not the slightest ground for assuming the existence of a new growth penetrating into the tissue."

The above cablegram conveys most gratifying information concerning the present condition of the Crown Prince, and it effectually allays anxiety as to the grave possibilities which the earlier reports led the public to fear were involved in the case. It also fully confirms the favorable opinion which Dr. Mackenzie and Prof. Virchow had formed of the character of the morbid growth on the vocal cord, and justifies Dr. Mackenzie's belief, expressed at the first consultation in Berlin, in the feasibility of its successful removal by intralaryngeal operation.

THE SPREAD OF SCARLATINA AND TUBERCULOSIS BY MILK.

THE recent lecture of KLEIN before the Royal Institution of London, established beyond reasonable doubt the conclusions drawn from his previous researches and those of POWER, regarding milk as a medium of direct contagion in scarlatina. It will be remembered that for several years past the suspicion that milk might be the carrier of scarlatina and other diseases has been rife in England; but the epidemic of 1885, near London, and the exhaustive study made by Power at that time, have demonstrated conclusively that diseased cows at Hendon farm communicated to their milk a substance which caused the disease in those consuming it. It could not be ascertained where these cows became infected, nor whether those who bred or reared them were the subjects of disease. Upon the teats of the diseased animals ulcers, varying from a quarter to three quarters of an inch in diameter, were found, which were covered with a brownish scab, and had granulating, slightly indurated bases. Observation showed that small vesicles made their appearance on a reddened, greatly swollen teat, which became ulcers in a couple of days. As a rule, the disease affected the teats only, but sometimes attacked the lower portion of the udder also. Matter from these ulcers and their scabs produced a similar disease when inoculated in other animals. In this matter a streptococcus was found, whose cultures in agar agar and gelatine produced the disease by inoculation in calves, which revealed the lesions of scarlatina on post-mortem examination.

Klein's recent experiments embraced the inoculation of animals by virus obtained from the human being, and also from the animals at Hendon, and their results corresponded, both in gross and microscopic appearances, and also with the results of culture experiments with germs procured from both sources.

Among the interesting pieces of corroborative evidence was the finding of the micrococcus in a cheap quality of condensed milk, and the production of the disease by cultures of this material. The chain of proof was sufficiently strong for Klein to conclude that "The *micrococcus scarlatinæ* is the cause of human scarlet fever; that it produces in bovine animals a disease identical with the Hendon disease and human scarlet fever, and that while the cow is susceptible to infection with human scarlet fever, it can, in its turn, be the source of contagion for the human species." Contagious matter is introduced into the milk by pressure upon the ulcerated teats during milking.

Klein's report has led to earnest discussion in England, where the purity of food is a subject of constant study and legal supervision.

JAMIESON and EDINGTON, of Edinburgh, have recently made observations upon the scarlatina germ as obtained from the human subject. The blood was examined as early as possible in a case of scarlatina, and the presence or absence of the

germ noted. An area of skin was then selected, sterilized, and protected from contamination until desquamation occurred, when the rejected epithelia were examined for the bacilli. With cultures made from the germs found in desquamated epithelia they produced scarlatina in animals, whose blood yielded bacilli giving characteristic cultures. Their investigations have not been carried sufficiently far, as yet, to be compared with those of Klein; but are of great interest and value. While it is true that there are several vesicular diseases of cows' udders which are not always clearly differentiated, some of which may be innocuous to human beings, yet the chain of evidence offered by Klein leaves little room for doubt that the streptococcus he has found causes human scarlet fever.

An added danger in the use of milk from diseased animals was emphasized by a report given by GAUTIER to the French Academy of Sciences at a recent meeting. He has studied the transmission of tubercular infection by milk and cheese from tuberculous cows. He produced tuberculosis in rabbits by these materials; and after an extended series of experiments he concludes that not only tuberculous milk, but the substances made from it and used for food contain infectious matter. A human being may be inoculated with tubercle by consuming tuberculous milk in the form of fresh milk; curdled or "clotted" milk; fresh cheese; dried or salted cheese; or curds and whey. Fowls and pigs may be also inoculated by such milk, and he explains the frequency of the disease in animals partly on these grounds. He advises the greatest caution in the use by human beings of milk from tuberculous cows; and also that all milk fed to fowls and pigs be thoroughly boiled.

We may obtain an idea of the frequency of tuberculosis in cows from the statement by BLAINE and EDSON, of the Health Department of New York, that two per cent. of all animals slaughtered at the abattoirs of New York, and twenty-one per cent. of all milch cows, have tuberculosis.

MILLER, State Veterinary Surgeon of New Jersey, reports to the Bureau of Animal Industry at Washington, that tuberculosis is affecting cattle in eight counties of New Jersey; the number of herds reported being fifty-three. Finely bred cows, giving large quantities of milk, are most often affected, and frequent examples of heredity are seen. The meat of such animals, as well as the milk, is frequently sold, and is a ready means of contagion.

Systematic, thorough examination of all foods is a crying need. The recent opening of a model dairy near London, at which a number of distinguished medical men were present, indicates the proper attitude of the profession on this subject. Veterinary medicine is steadily advancing among us, and the vigilance of the law and the hearty cooperation of medical men are needed to close avenues of attack to the most deadly enemy of human life.

SANGER'S OPERATION.

THE application of the principles of conservative surgery to obstetrics has produced an operation whose results challenge consideration. A modification of the classic Cæsarean section, it deals successfully with the most serious complications of parturition. Since its first performance in 1880, out of 53 cases operated upon, 37 mothers and 47 children have been saved, a gain of 30 per cent. over the results of Porro's operation, up to that time the best procedure known. Nearly all these successes have been attained in the maternities of Dresden and Leipzig, where the operations have been performed by different men, but under one plan. While parts of this method had been used by others in various operations, yet Sänger is proved by his own writings and by the critical studies of Harris, to have first instituted and clearly defined the operation which bears his name.

Sänger's purpose, and his method of accomplishment, as stated in a communication to the *American Journal of Obstetrics* for June, 1887, will be found in the "Progress" columns of this issue of THE NEWS. The operation is to be done early; to be antiseptic; and eventration of the uterus, temporary compression of the lower uterine ligament by rubber ligature, and the details of ventrotomy are to be carefully observed.

The most frequent indication for the operation is contracted pelvis; and Credé, recently reporting the seventh successful case at Leipzig, in the *Archiv für Gynäkologie*, Band xxx., Heft 2, states that of cases of this kind operated upon 82.5 per cent. recover. A successful case at Erlangen is reported in detail in the same number by Döderlein.

In America 7 operations have been done; 1 mother and 4 children have recovered; mortality, mothers, $85\frac{5}{7}$ per cent.; children, $42\frac{8}{9}$ per cent. The successful operator is Lusk, of New York, whose case was reported in full in THE MEDICAL NEWS of May 7, 1887, page 527. These statistics contrast forcibly with the German, $88\frac{2}{10}$ per cent. of mothers having recovered, and $94\frac{1}{10}$ per cent. of children. The fondness of American obstetricians for efforts at forceps delivery in contracted pelves, and tardiness in operating, and lack of well-trained assistants, may be reckoned among the causes of this mortality.

Credé's report of the examination of the patient, two months after recovery, whose case he describes, is interesting: "I found the abdominal cicatrix a fine, straight line, without enlargement, freely movable in all directions; the aponeuroses and integu-

ment adherent. The uterus was entirely separated from the abdominal cicatrix; it was small, not sensitive, and freely movable. Menstruation had recurred eight weeks after recovery."

The great superiority in the results of Sänger's over the Porro-Müller operation indicates its performance in all cases demanding Cæsarean section, except those in which the uterus is in such a condition that its removal is imperative; as after prolonged labor, after exhaustion and unsuccessful attempts at instrumental delivery *per vaginam* had induced uterine atony and beginning decomposition.

For those who object to giving to an operation a personal name the title Cæsarean section, with multiple seroso-serous suture, has been proposed, and we think describes the essential characteristics of this operation.

THE CONTAGIOUS DIARRHŒA OF NURSING CHILDREN, AND ITS BACILLUS.

HAYEM recently reported to the Academy of Medicine some investigations which he had made to determine the nature of the contagious element in the diarrhœa of nursing children, and its most efficient treatment. He was led by the failure of general medication to prevent relapses, to order all bedding and linen of the little patients to be disinfected with bichloride of mercury, when he observed that the disease, which had become epidemic, was checked.

An examination of the dejecta showed that the greenish color present was dependent upon masses of bacilli and substances formed by them. Cultures were readily made of these microbes, and their behavior toward various antiseptics observed. The reaction of the matter in which they were voided he found was neutral or alkaline; and accordingly the effect of acids was tried. It was found that lactic acid, even in small quantities, destroyed the cultures made upon peptonized gelatine.

In doses of a teaspoonful of a solution of two parts to one hundred of water, given a quarter of an hour after nursing, and repeated from five to eight times daily, lactic acid gave excellent therapeutic results, surpassing naphthalin, iodoform, sulphide of mercury, and calomel.

Hayem concludes that altered gastric secretions, in the dyspepsias of nurslings, permit the microbes to enter the intestine with their germinating power undestroyed; and finding there an alkaline medium of growth, they increase rapidly. He considers that the dejecta, as received upon linen and bedding, contain the contagious elements. He has instituted experiments upon young animals with the cultures obtained from his patients, the results of which will be of interest.

VIGIER recommends in the *Gazette Hebdomadaire*, June 17, 1887, the following formula:

R.—Acid. lactici	. . . .	2 parts.
Syrup. simpl.	. . . .	98 "
Essentiæ citronis	. . . .	q. s.—M.

Filter.

Sig.—2 or 3 teaspoonfuls daily.

Koch has already shown, in his studies of the comma-bacillus of cholera, that they are killed by the lactic acid of the normal gastric secretion, and that it is when the activity of this physiological safeguard is interfered with or destroyed that the bacilli pass uninjured into the intestines, to multiply and produce the characteristic disturbances there. The effects of lactic acid upon these microbes, and the recent investigations of KOLISCHER, of Vienna, upon the tubercle bacilli as affected by phosphoric acid, suggest the acids as a class of germicides whose study promises information of practical value.

THE yellow fever at Key West appears to be on the increase. Three new cases were reported on Tuesday and three deaths.

DR. JOSEPH D. BRYANT, Professor of Anatomy and Clinical Surgery in Bellevue Hospital Medical College, has been appointed by the Mayor of New York a Health Commissioner, *vice* DR. Woolsey Johnson, deceased.

THE Gross Medical College has been organized at Denver, Colorado. It is the Medical Department of the Rocky Mountain University. It announces a collegiate term of seven months, beginning September 21st next. Professor Clayton Parkhill is Secretary of the Faculty.

REVIEWS.

A TEXT-BOOK OF MEDICINE FOR STUDENTS AND PRACTITIONERS. By ADOLF STRÜMPELL, formerly Professor and Director of the Medical Policlinic at the University of Leipsic. Translated from the Second and Third German Editions by HERMAN V. VICKERY, M.D., and PHILIP C. KNAPP, M.D., with Editorial Notes by FREDERICK C. SHATTUCK, M.D. New York: D. Appleton & Co., 1887.

UNDOUBTEDLY one of the best of modern text-books of medicine in the German language, is that of Strümpell, formerly professor at the Medical Policlinic in Leipsig. It is, therefore, with great pleasure that we welcome its translation into English by Herman F. Vickery and Philip C. Knapp, with editorial notes by Frederick C. Shattuck.

The translation is accurate without being too literal. There is no attempt to drag German idioms into the English language, but the English itself is idiomatic. The treatment has not been adapted to the United States

Pharmacopœia throughout notes giving the formula of distinctly German preparations have been added whenever necessary, and all measures except those of length have been changed from metric into English denominations.

The work is too large to give any detailed account of its contents. The chapters on acute infectious diseases occupy 109 pages; those on diseases of the respiratory organs 166, with other affections in a corresponding ratio.

Strumpell's text-book is probably most highly thought of for its chapters on the diseases of the nervous system; and the translators have increased the value of this portion of the work by adding foot-notes containing the results of investigations made since the last German edition was published. Numerous valuable and judicious notes by the editor are also scattered throughout the work, but not to an extent sufficient to interfere in any way with its individuality.

The therapy is not in all respects exactly that to which Americans are accustomed, but this fact is rather an advantage than otherwise, as tending to make us more cosmopolitan in our knowledge. It can be said with assurance that the purchaser of this text-book will not have cause to regret his investment.

L'Amputation du Membre Supérieur dans la Contiguité du Tronc. (Interscapulo-thoracic Amputation.) Par Paul Berger, Chirurgien de l'Hôpital Tenon, Professeur Agrégé a la Faculté de Médecine, etc. Paris: G. Masson, 1887.

Interscapulo-thoracic Amputation of the Upper Extremity. By Paul Berger. Paris, 1887.

With commendable industry Prof. Paul Berger, of Paris, has collated all the literature extant, bearing upon the subject of total ablation of the upper extremity and scapula, and has presented the results of his researches in the above mentioned monograph. So far as appears, the upper extremity and scapula have been removed fifty-one times, for various causes, such as tumors of the humerus or scapula, osteitis, and gunshot wounds, with a variable degree of mortality, about 20 per cent. succumbing after operations performed for the removal of diseased conditions, whilst 30 per cent. of traumatic cases die.

The operation has been performed eleven times in America, the first operator having been Prof. Dixi Crosby, of Hanover, N. H. The combined mortality from all operations is about 25 per cent., but probably the improved methods of antiseptic surgery introduced within recent years would materially lessen this mortality. The dangers to be apprehended are those incident to operations in the proximity of large bloodvessels, hemorrhage, entrance of air into the veins, and shock, and all are more or less preventable. Strange to say, the mortality after secondary removal of the scapula is equally as great as that of complete removal of the upper extremity and scapula at one operation. Not infrequently a large portion of the clavicle has been removed at the same time. Notwithstanding that cases of accidental separation of the upper extremity and scapula had been known since the time of Cheselden, it was not until 1808 that any surgeon deliberately removed these structures as a therapeutic resource. In this year, Ralph Cumming, an English naval surgeon practised for the first time the simultaneous ablation of the arm, scapula, and clavicle for a gunshot wound, the patient surviving. To anyone desiring information in regard to this useful but rare operation, we heartily commend this treatise, which is a complete study, historical, critical, and practical, of the whole subject.

SOCIETY PROCEEDINGS.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, April 30, 1887.

The Vice-President, Charles K. Mills, M.D., in the Chair.

Dr. Landon Carter Gray, of Brooklyn, read, by invitation, a paper on

SYPHILIS OF THE NERVOUS SYSTEM, AND ITS TREATMENT.

(See page 33.)

Dr. H. C. Wood said that there were only two points in this interesting paper on which he felt disposed to speak. First, with reference to the connection between migraine and epilepsy. This theory dates back especially to Trousseau, who, as we know, gave the name of epileptiform neuralgia to migraine. Migraine certainly does occur in epileptic patients, but he doubted if it occurs more frequently in this class than in the community at large. He could not remember to have ever seen an epileptic patient who also suffered with migraine, nor had he ever seen a patient with migraine affected with epilepsy. It is entirely possible for an epileptic discharge to be sensory occasionally, but he thought that true epileptic migraine must be exceedingly rare. In regard to the use of mercury, he was much surprised at the position taken. He fully agreed with the author as to the value of iodide of potassium in nervous syphilis. He had, however, never used it in doses as large as Dr. Gray mentioned. He rarely exceeds one-half an ounce, and he thought that three hundred grains in the twenty-four hours will accomplish all that a larger dose will. In cases where time is an element of importance, mercury will accomplish all that the iodide does, and do it in a shorter time. He recalled one case seen in consultation with Dr. Mills which brought the importance of time clearly before him. They were giving large doses of iodide of potassium, and the man was steadily improving, and undoubtedly would have recovered if he had not died as the accidental result of an epileptiform convulsion. The convulsions were becoming less frequent and less severe, but on one occasion the fit stopped his breathing a little too long, and he died.

Nervous syphilis may be an early manifestation of syphilis, and he thought that all syphilographers agree that early syphilis yields better to mercury than to iodide of potassium. Again, in advanced syphilis, in iritis, we know the effect of mercury in causing the absorption of gummatous deposits. It is unreasonable to suppose that gummatous infiltrations in one situation will have a different relation to iodide of potassium and mercury from that which they will in another. Brain syphilis is amenable to exactly the same treatment as syphilis of any other portion of the body. The brain element has

little to do with it. It is the syphilis we have to treat. Therefore, in all cases where the symptoms are very urgent, and where there is danger from the accidental interference with the function of a vital part, he thought that mercury should be pushed until ptyalism is produced. After that the iodides may be used. There also often comes a time in nervous syphilis when the iodide should be replaced by the tincture of the chloride of iron with the bichloride of mercury: twenty or thirty minims of the former with about one-twelfth of a grain of the latter. This will often effect a marked change within twenty-four hours.

Dr. Osler said that his experience with these affections has been somewhat limited. He has had considerable difficulty in determining whether an arterial lesion at the base of the brain was really a specific lesion, or whether it was an ordinary arteritis. He called to mind one case in which this difficulty arose. A man aged thirty years had the primary lesion eighteen months before his death. He had been treated for severe secondary symptoms and suddenly died from hemorrhage at the base of the brain. The first portion of the basilar artery was dilated and in a small region eroded and perforated. In the central portion of the basilar artery there was a nodular growth which partially obliterated a portion of the vessel. This was an early date for syphilitic arteritis to come on. The statistics of Heubner and others show that it is usually a late lesion of syphilis, although, as Dr. Wood has intimated, it may occasionally appear at an early date. In those instances in which, in addition to the arteritis, there is more or less meningeal thickening, there is less difficulty, although in one instance there was a doubt whether the lesion were syphilitic or tuberculous. In that case he thought that section of the arteries showed conclusively that the lesion was syphilitic. There are only two conditions in which we meet with fusiform nodular swelling of cerebral arteries—*i. e.*, in syphilis and tuberculosis. On section of the syphilitic nodules, the growth is always subintimal, and proliferation is entirely between the fenestrated coat and the endothelium, whereas, in the tubercular nodules, the infiltration is almost always adventitial. He had seen only one instance of multiple gummatous growths of the brain. In this case there were three growths attached to the meninges, varying in size from a marble to a large walnut. The remarkable comatose conditions which occur in connection with cerebral syphilis are of great interest. In one case in which there was a tumor of the brain, where the diagnosis of cerebral syphilis had been made by several neurologists, the periods of somnolence lasted from three to six weeks. He agreed with Dr. Wood as to the great value of mercury, particularly in the early stage of certain of these cases.

Dr. E. N. Brush said that his attention was first directed to this subject by an attack of nervous syphilis in a medical friend. Nervous symptoms came on seven years after inoculation of his thumb by the original lesion. Speaking from his experience in the treatment of syphilitic diseases in general, he was sorry that he could not agree with Dr. Gray in regard to the inutility of mercury in the treatment of nervous diseases connected with syphilis. He agreed with him in regard to the value of iodide of potassium in large doses, perhaps not, however, of the size he advocates.

Dr. Gray has briefly referred to general paralysis of the insane as due to syphilis. Some one has said that probably eighty per cent. of brain diseases occurring between twenty-five and forty are due to syphilis. He was unable to speak as to the correctness of this statement, or as to how often syphilis is productive of paresis, but in a large proportion of the cases of general paresis that he has seen there has been a history of syphilis. With regard to prognosis in paretics with syphilitic history, he has come to think that many of these patients live longer if we do not pursue a too active treatment. His plan has been to keep a mild course of what has been called mixed treatment—small doses of mercury with medium doses of iodide of potassium.

Dr. Wharton Sinkler, while he did not underrate the value of mercury, said that his preference has been for iodide of potassium. The use of mercury is attended with some inconveniences, such as diarrhœa and ptyalism, and he has seen its use followed by the breaking down of old sores. He agreed with Dr. Gray as regards the unfavorable prognosis in cases of locomotor ataxia from syphilis. Many think that because a lesion is syphilitic it will yield to antisyphilitic remedies. His experience is that locomotor ataxia, due to syphilis, is as untractable as locomotor ataxia not due to that cause.

Dr. Francis X. Dercum said that an interesting case which he has recently seen illustrates the point that locomotor ataxia, whether due to syphilis or not, should not be considered incurable. A case presented itself at the University Dispensary two or three years ago presenting the typical symptoms of ataxia to a marked degree. There was a possibility of syphilis, but no clear syphilitic history. He was at first placed on the mixed treatment and the iodide pushed without benefit. He was then given small doses of mercurials and this has been followed by marked improvement. The man is now able to walk without assistance. The element of time is often overlooked in these cases. After removing the infiltration of the nerve tissues, a certain time is required to permit the rebound of the depressed nervous tissues. Even when the lesions are cured the patient is not relieved of the profound impression made upon the entire organism and especially upon the nervous system.

Dr. J. Hendrie Lloyd had been unable to obtain any positive and definite views with regard to the relation of dementia paralytica to syphilis. The course of reasoning seems to be that because a patient with dementia paralytica has a history of syphilitic infection, therefore he has a syphilitic brain disease and the prognosis is favorable. This is a practical question, which has come home to this city in a very positive manner within the past few months, in the case of a prominent official. If we assume the case to be syphilitic, are there any characteristic histological or pathological lesions showing such to be the case? If we decide that a case of dementia is syphilitic in origin, have we a hopeful case for therapeutics? He thought that if we have the well-marked symptoms of dementia paralytica, we are justified in stating that the prognosis is exceedingly doubtful, whether the patient has had syphilis or not. In the autopsy of a well-known tragedian who had general paresis, he saw well marked the endarteritis described by Heubner; but there was in addition the evidence of a lepto-meningitis, or a cortical cerebritis,

as shown by marked opacity of the membranes and adherence of the gray matter to the pia mater, so that the cortex tore off with the pia. Dementia paralytica never depends merely upon an endarteritis of the large vessels, and this endarteritis might be difficult by itself to distinguish from such a condition as arises in gouty and other subjects.

Dr. H. C. Wood said, with reference to the points suggested by Dr. Lloyd, that he had come to some positive conclusions in his own mind, which have been verified by experience. In the case referred to, he said one year ago, that man had either brain syphilis, or dementia paralytica. We have, on the one hand, locomotor ataxia, due to sclerosis of the posterior columns of the spinal cord. In a large proportion of cases, this comes on in syphilitic subjects. The exact relation of the syphilis to the lesion is a matter of conjecture. The important clinical fact remains that if we have sclerosis, whether it occurs in a syphilitic or non-syphilitic person, it is not amenable to treatment. Dementia paralytica also occurs to a large extent in syphilitic individuals. We have, on the other hand, certain cases in which symptoms closely resemble those of locomotor ataxia, and are directly due to syphilitic alteration in the spinal cord, and are amenable to treatment. In another set of cases, the symptoms closely resemble those of dementia paralytica, but are really the direct result of syphilitic disease of the brain. We have these two sets of cases.

The practical point is, Can we in any given case determine whether we have the direct effects of syphilis or not? He thought that in the majority of cases a fair guess can be made. The symptoms of the syphilitic case are usually a little abnormal. For instance, he had a case resembling locomotor ataxia, but there were also epileptiform convulsions. He said this is a case of syphilitic disease.

So in apparent dementia paralytica, the man may have the delirium of grandeur, but he has other symptoms which do not belong to the true disease. This aberrancy from the usual type points toward syphilis. The only safe method is to give a guarded opinion.

Dr. W. D. Robinson had now under his care a case of locomotor ataxia in which the diagnosis was confirmed by a number of prominent clinicians. This case has rapidly improved under the use of hydrobromate of hyoscine. When he came under his care the paralysis was almost complete. In order to relieve the pain he was taking six grains of morphia a day and three pints of alcoholic stimulants. He began with $\frac{1}{200}$ of a grain of hydrobromate of hyoscine every six hours. At the end of the month the morphia was done away with and the alcohol was reduced to one pint. The suffering was greatly relieved. The hyoscine was gradually increased until its physiological effects were induced. The ability to associate volition and motion began to return, and at the end of three months massage and electricity were added to the treatment. He then began the use of mercury. The man is now able to stand alone and with assistance is able to make a few steps. He would ask if Dr. Gray has found that syphilitic nervous disease has had a tendency to induce an uncontrollable appetite for alcohol. He had seen two or three instances in which this was claimed to be the case.

Dr. Mills said that Dr. Gray had referred to the occurrence of cephalalgia with hemiplegia, and the disappearance of the headache on the occurrence of the hemiplegia in a certain number of cases. He had observed the same thing, and some years ago, in a clinical lecture, advanced a view for its explanation. Usually in these cases there is a syphilitic tumor connected with the membranes. As the growth advances, it obliterates, by pressure and inflammation, the vessels which go to the part and there is breaking down behind the growth. This relieves the tension, and thus the headache is relieved. He had seen cases where the post-mortem indicated that this was the correct explanation. With reference to paretic dementia, his experience has been that where the disease is well developed the prognosis is as bad in a syphilitic as in a non-syphilitic case. The case is probably incurable, although there may be remissions. More stress should be laid on the element of time and fine tissue change than has been done. Dr. Gray has called attention to the fact that whether the cerebral syphilis is of the nature of a gumma, disease of the membranes, or endarteritis, there are certain foci of softening from the obliteration of vessels. These cannot be replaced any more than absolute tissue loss can be replaced anywhere else. He believed that the prognosis is always bad where there was widespread disease of the blood-vessels. The cases of locomotor ataxia which are said to be curable, he believed were not cases of spinal sclerosis. Often they were not even cases of spinal disease. He had seen cases which were undoubtedly examples of cerebellar disease, and even of cerebral disease. Dr. Wood relies on the presence of aberrant symptoms as indicating a probable syphilitic origin. If you have such aberrant symptoms, the chances are that the disease is not in the spinal cord.

In the treatment of syphilis of the nervous system he used both mercury and iodide of potassium. There are at present cases in the Philadelphia Hospital which illustrate the rapid improvement that may take place under the use of mercurial inunction. After the case had advanced to a certain point under the use of mercury, his plan was to substitute the iodide. In the cases that have advanced very far the iodide was the best remedy.

Dr. Gray, in closing the discussion, said, with regard to the use of mercury, that he had seen over and over what he had stated in his paper, that cases of syphilis of the nervous system that do badly under the use of mercury do well under the use of the iodides. He did not deny that some cases possibly may be cured with mercury, but he has never seen such a case. The iodides will do all that mercury will do; they will do more; and you can rely on them when you cannot rely on mercury.

With reference to Dr. Wood's statement that migraine is very infrequently conjoined with epilepsy, his experience has been very different. He could readily recall eight cases in which epilepsy was conjoined with migraine. He would say that the most frequent form of epilepsy is that in which loss of consciousness is conjoined with clonic and tonic movements. Next in frequency he would place epilepsy associated with migraine, and petit mal last.

In regard to the diagnosis of the arterial lesions of

syphilis, he believed that in certain cases it is not possible to make the diagnosis from the microscopical appearances alone. The limitation of the infiltration between the fenestrated coat and the intima occurs in other forms of endarteritis. Unless something is obtained from the studies of the bacillus, he did not see how it is possible to make a positive diagnosis from the microscopical appearances alone.

Dr. Wood relies on the aberrancy of the symptoms as indicating that in general paralysis the condition is due to syphilis. We are not acquainted with the pathology of this disease, but we know that the lesions, whatever they are, are limited to the cortex of the brain and the overlying pia mater. The pia mater contains the bloodvessels which dip down and form anastomoses in the region of the pyramidal cells. Some German investigator claims that there are very fine commissural fibres within the gray matter of the cortex, and that the affection starts in these fibres. The symptoms of a typical case are somewhat like these: a man will have, at varying periods of time, inequality of the pupils. This is often difficult to make sure of. Then there will be tremulousness of the tongue and facial muscles; then a certain thickness of speech. Now we may get the delirium of grandeur, but in the majority of cases we do not get that in the early stages. We can get precisely these symptoms from other affections. They may be brought about by meningitis due to alcoholism, trauma, or by traumatism in a syphilitic individual. It is impossible in the early stage, unless we can exclude all other conditions, to make a positive diagnosis. He thought that in general paresis and in locomotor ataxia, a large proportion of the cases occur in syphilitic subjects, and that there is about the same relation between syphilis and locomotor ataxia as there is between certain infantile paralyses and the febrile disorders of childhood. They are post-febrile disorders; so these are post-syphilitic disorders.

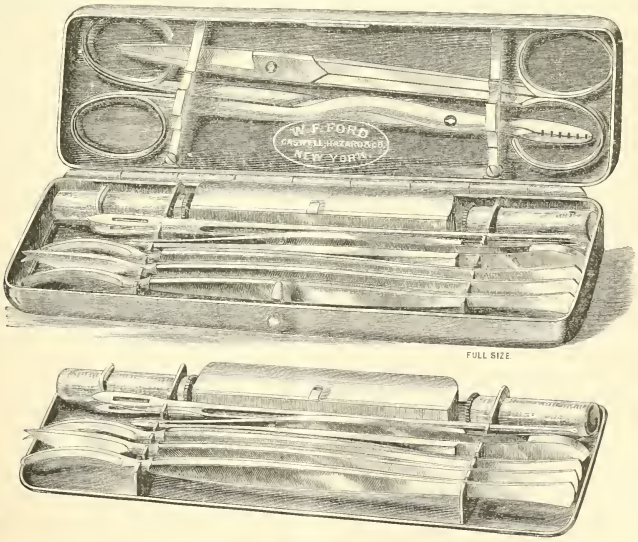
With reference to the induction of an appetite for alcohol by syphilitic disease of the nervous system, he had had no experience. He thought that the point made by Dr. Mills, that some of the cases set down as locomotor ataxia are not instances of this disease, is a good one. A German author recently gave the interesting history of a case in which there was syphilitic myelitis. The myelitis was peripheral, forming a narrow ring around the cord. This case presented many of the symptoms usually ascribed to locomotor ataxia.

NEW INVENTIONS.

AN ANTISEPTIC POCKET-CASE OF INSTRUMENTS.

BY ROBERT F. WEIR, M.D.,
OF NEW YORK

I HAVE been using, for nearly a year, an antiseptic pocket-case of instruments, and this time-test has fairly proven its usefulness. In this age of surgical cleanliness, it must have been brought home to many that the



FULL SIZE.

closed instruments in the ordinary velvet-lined pocket-case are hard to keep clean, and free from being possible sources of infection to a wound. This particularly applies to the case itself, which often becomes not only dirty in the ordinary sense of the word, but also contaminated with the hasty contact of blood- and pus-stained fingers in the various emergencies in which a pocket-case is used. I have long felt this blot upon my unexpected surgical work, and have at length overcome the main difficulties in the way.

The pocket-case now presented has been made under my directions, by Ford, of New York. It is of metal, and by the omission of such instruments as a hernia knife, gum lancet, etc., the purposes of which can as well be carried out by the more ordinary knives, it has been reduced in size until it now measures five and a half inches long, two inches wide, and only three-quarters of an inch in thickness. This permits it to be readily carried in the vest or hip pocket. The annexed woodcut shows not only the actual size of the case, but also its contents. These may be varied to suit the ideas of different surgeons. As before stated, I have found by actual experience, that my surgical demands upon it have satisfactorily shown its competency.

It contains, as will be seen, but three knives, a scalpel, a sharp- and a probe-pointed bistoury. These are made out of a single piece of steel, with small handles to lighten their weight. Should a larger handle be desired, the wooden handles plated over with nickel, as now used in Hamburg, can be best resorted to. Next is a fine-pointed pair of thumb-forceps, and beyond this is a slot in which rest two silver probes and a steel director curved and eyed at one end, to serve as an aneurism-needle. Two small bottles, with rubber corks, to hold antiseptic catgut and silk, with a box for straight and curved needles, make up the lower part of the case, which can be lifted out entire by the button at one end, and thus allows of ready access and cleansing, and also of immersion in a carbolic solution. I may here remark that the straight Hagedorn needles should be tried by every surgeon, if not already resorted to, because of their ease of penetration, and also because their large eyes permit the carrying of catgut better than other needles of similar size. The curved needles of the same surgeon are better known, and possess the same qualifications.

In the lid of the case are found a pair of scissors and a dressing-forceps; the blades of each are on a pivot-joint, and separable. The forceps combine three instruments in one: a dressing-forceps of the ordinary type, a hæmostatic forceps, and needle-forceps, the deep transverse grooves suggested by Dr. Abbe, making the best and simplest holder of the Hagedorn needle that we have.

This case, I am informed by Hazard & Hazard, can be furnished at eighteen dollars, being nearly the same as the price of the ordinary Russian leather pocket-case.

CORRESPONDENCE.

LETTER FROM FLORENCE.

A Porro-Cesarean Operation—Laparotomy Statistics.

I ESTEEM myself singularly fortunate in having had an opportunity to witness a "Porro" operation before leaving Florence, and although I cannot give such an account of the case as to render it of scientific value, I have no doubt that the new technique will be of sufficient interest to your readers to justify my describing it.

The operator was Dr. Giulio Kirch, a Florentine by birth but of German parentage, for three years an assistant to Prof. Chiara, and since recently settled in a neighboring town. I had an intimation of the case coming on and promise of an invitation but with slight hopes of being found. However, I was at lunch when the messenger came, and in a short while found myself in a small omnibus and on the way, packed in with instruments and apparatus, two female nurses of the hospital, and two young physicians, Dr. Martinetti, assistant of the Obstetrico-Gynecological Clinic, and Dr. Emilio Fasola, who was mentioned in my last letter as having had a successful Porro operation.

Landscape scenery does not usually enter into the report of a surgical case, but an exception may be claimed this time from the exceeding beauty of the ride. We crossed the Arno and beyond the suburbs began to ascend, the road winding up the mountain side, at every turn presenting delightful views over vineyards and olive orchards, of Florence, the valley, and the swelling hills and mountains beyond. It was like an Alpine ride except the lack of snow-covered peaks above. After reaching the summit we descended for quite a time into a valley as widespread, as undulating, and as beautiful as that of the Arno. At the end of about two hours and a half we turned into a country lane, and after driving through a vineyard stopped at a peasant's isolated house on the hillside where we found Dr. Kirch and a physician of the vicinity.

It required but slight examination to show that the exigencies of practice are just the same on one side of the ocean as the other. We ascended a rough stone staircase to a small chamber, under the brown rafters of which the operation was to be performed. The room was lighted by six panes of seven by nine glass. The floor was of large brick tiling about one-fourth of it so sunken that the given warning was not needed to keep us off it, and so to preserve us from precipitation to the room below. The furniture of the house was exhausted in preparing a table upon which to lay the patient and but one small stand could be had for instruments.

Soon all was ready, two spray apparatus were in operation, and the patient, under chloroform, was brought in from an adjoining apartment. She was a dwarfed young woman of twenty-four, unmarried, markedly rachitic from her short and crooked legs, but with a good country color in her cheeks. She had been in labor since morning—about ten hours. The abdomen was thoroughly washed with soap and solution of carbolic acid, the pubes shaved, and a vaginal disinfectant douche administered. I was kindly permitted to make an examination, but with the caution not to rupture the membranes. As I found them protruding well into the vagina, dilatation of the cervix being complete, of course I could not ascertain the character or extent of the pelvic deformity. The abdomen having been opened in the median line, from a little above the umbilicus downward, four sutures were passed through the walls at the upper part of the incision; these to draw the opening together and prevent escape of the intestines if necessary. The uterus was then carefully

palpated and an extremity of the child being recognized, the organ was incised. The hemorrhage at this period became very free, but not dangerous, although very much obscuring a view of the parts. The incision was rapidly prolonged, the membranes rupturing and liquor amnii escaping, and the child promptly extracted by the feet. It was a large, well-formed, male child, and after some vigorous treatment from the nurse, who received it from my hands, it began crying lustily. The uterus was now turned out of the abdominal cavity, the cervix above the vagina carefully made out, and a large needle armed with a strong elastic ligature was passed through it. Another large needle, unarmed, was passed through the cervix and left in situ. The ligature was then drawn tight around each half, the two strands being fastened by silk ligatures instead of being tied in a knot, the elastic ligature passed again around the whole pedicle and fastened in a similar manner. The upper three-fourths of the uterus containing the placenta was then cut away. This part of the operation took, of course, far more time than that of the removal of the child, and still more time was occupied in testing the accuracy of the ligatures and in cleansing the abdominal cavity, into which, however, but little fluid had entered. When all seemed satisfactory, the remnant of the uterus was trimmed down, that and the wound well dried and dusted with iodoform, and the abdomen closed, particular care being taken to approximate the edges with silk ligatures passed close to the projecting pedicle both above and below. The outside dressing was the same as described after ovariotomy, including the quilted pad with shot.

When the patient was placed in bed and had recovered from the chloroform, her condition was excellent; she had a good pulse, a good countenance, and no evidence of shock.

The selection in this case of the Porro operation instead of the improved Sänger method, was rather, so far as I could gather, with the view of future possibilities than anything else. The doctor recognized the Porro as the far more severe operation, and one far more difficult to perform. I will make arrangements before I leave to obtain information as to the termination of this case, and send word of the mother's fate. R.

FLORENCE, May 26, 1887.

Before leaving this city I am happy to be able to send word as to the result of the Porro operation described in my last. It has proved a complete success. The temperature never showed any considerable rise and on the tenth day, when last heard from, she was considered out of danger. The child also did well. This result is particularly gratifying under the circumstances, the surroundings of the patient having been sufficiently indicated, and neither of the trained hospital nurses having remained with her, care and attention of every kind devolved upon the doctor himself.

I am also able to give you the number of laparotomies performed by Prof. Chiara, in the hospital, during the years 1885 and 1886, with results. I expected to be able to give the different kind of operations, as ovariotomies, etc., but cannot do so. Still, the statistics are not without interest.

Number of operations	38
Number of deaths	6
Causes of death:	
Pelvic tuberculosis	1
Septicæmia	3
Vomiting	1
Hemorrhage	1

In the description of the ovariotomy it should have been stated that the pedicle, after having been ligatured, was thoroughly charred with the thermo-cautery. R.

FLORENCE, June 11, 1887.

NEWS ITEMS.

PASTEUR'S TREATMENT IN BELGIUM.—The report of a commission appointed by the Belgium Government to report upon the establishment of an institute for Pasteur's treatment, is adverse to such a proceeding.

THE PENNSYLVANIA STATE MEDICAL SOCIETY elected Dr. R. J. Levis, of Philadelphia, President for the ensuing year, and decided to hold its next annual meeting in Philadelphia on the first Wednesday in June.

VON LANGENBECK, the distinguished German surgeon, has been successfully operated upon, the second time, for cataract, by Dr. Pagenstecher.

THE SPREAD OF PASTEUR'S TREATMENT.—In a letter replying to von Frisch, of Vienna, written on May 29, 1887, Pasteur declares that there are fourteen "institutes" where his treatment is carried out daily.

THE MORTALITY AMONG NURSES IN LYING-IN HOSPITALS.—The investigations of DOHRN, of Königsberg, have shown that the mortality among nurses in lying-in hospitals in which clinical instruction is given, is two or three times as great as that in similar institutions to which students are not admitted. Contagion introduced by students is considered the cause of this mortality, and more stringent government regulation of the admission of students to the German hospitals is urged.

M. ROBIN.—At the meeting of the Paris Academy of Medicine held on June 7, 1887, M. Robin was elected to membership.

HINTS IN PEPTONIZING MILK.—DR. BURROWS advises as follows in the *London Record* of May 16, 1887: As to the addition of water in the peptonizing process, adding water reduces the quantity of casein in cows' milk to that of mothers' milk; and besides this, serves an important office, in that *it prevents the action of the milk curdling ferment.* If water be not added, the rennet ferment present would curdle the milk, and then subsequently digest the curd. But in this case milk may be peptonized too much, and a bitter taste will be present.

Soda.—As to the addition of sodium bicarbonate, besides imparting to cows' milk the slight alkalinity natural to mother's milk, it affords the pancreatic digestive ferments a fluid resembling in reaction that in which they are normally active. *It also prevents the milk, if not fully peptonized, from curdling when boiled, for alkali albumins are not precipitated by heat.*

Cold and Boiling.—It should be stated that in predigesting milk boiling is advantageously resorted to when a discontinuance of the process is desired. If a peptonizing powder be added to a pint of milk, with a quarter or half a pint of water, and the whole allowed to stand in a small pail of water as hot as the hand can bear, at the expiration of from twenty to thirty minutes the milk will be peptonized sufficiently. If the milk be *not* then set on ice or boiled, peptonization will continue slowly, and the casein finally be wholly digested. If cows' milk be boiled, at the expiration of, say twenty or thirty minutes of peptonization, the casein will assume, on the addition of acid, a flocculent, flaky character, not unlike mothers' milk. Boiling destroys all digestive ferments. From all that one can judge, the results obtained with peptonized milk are of a satisfactory nature.

Dr. Keith and his Method of Operating.—Dr. Senn describes, from personal observation, Dr. Keith and his methods as follows:

When we realize the limited hospital advantages which are furnished him in the Royal Infirmary, we must admire the man who can show such results. The victories which have been so dearly bought at the expense of health, and in all probability of a portion of life itself, are the most appropriate and lasting monuments of an unselfish life spent in the interests of the profession of his choice and suffering humanity. In the Royal Infirmary he has sixteen beds and only one nurse. His son, Skene, is his assistant.

His operations are performed in a small room heated by an open grate fire, and but poorly supplied with light. Only a few students are invited to the operations. The patient is placed upon a board, to which she is fastened with a strap across the hips, and hands tied to it on each side; the board rests with each end upon a table, the operator and assistant standing one on each side between the tables. The room is disinfected before each operation with chlorine gas. The abdomen of the patient and hands of operator and assistant are washed with a strong alkaline solution for the purpose of removing the fatty substances, which, according to Keith, are carriers of the septic germs. After thoroughly washing the parts they are disinfected with a weak solution of corrosive sublimate. Sponges are used over and over, cleansing them after each operation in warm water, and subsequently in an alkaline solution; they are kept for use in a five per cent. solution of carbolic acid. During the operation they are kept immersed in a two per cent. solution of carbolic acid. The spray he has abandoned, since he has suffered from repeated attacks of hæmaturia, and if anything the results have been better since. Instruments are well cleansed after each operation, and during the operation they are kept in the strong solution of carbolic acid. All adhesions are carefully separated and each bleeding point tied with catgut. Ovarian cysts are tapped with a large straight trocar just as soon as the peritoneal cavity is opened.

From the descriptions I had read of his treatment of the pedicle I had always been afraid to adopt his method, but after I had seen the method applied I became convinced of its safety. The pedicle is firmly compressed in his clamp, and two or more cautery irons heated to a dull red heat are applied for a sufficient length of time to heat the metallic plates of the clamp sufficiently to cauterize gently the compressed portion of the pedicle. The compressed tissue must be rendered "dry," and when this has been accomplished it looks like a transparent membrane. Some practice is necessary to graduate the heat for each individual case, but when properly done hemorrhage never occurs. Dr. Keith affirms that the tissues thus treated do not slough, but are speedily supplied with new bloodvessels. He has seen new bloodvessels in the cauterized portion of the stump after twenty-four hours. Before the clamp is removed each side of the pedicle is carefully seized with forceps which do not tear, and any vessel which might contain blood is separately tied. In the many hundred cases treated by this method hemorrhage was never observed—certainly the best argument in favor of the reliability of the method.—*Journal American Medical Association*, May 14, 1887.

An Analysis of 1000 Prescriptions.—Dr. Forrest contributes the following in the *Reports of the New York State Pharmaceutical Association* for 1886, as the results of investigations in his pharmacy:

In 1000 prescriptions prepared at my establishment I find that 428 different kinds of articles were called for. Of these 428 articles 293 are officinal in the U. S. Pharmacopœia; 83 are unofficinal—that is, not recognized by the pharmacopœia, but the knowledge of their formulæ and their manner of preparation is possible to all druggists. 52 are proprietary—that is, articles followed with the name of their manufacturer, and generally secret preparations.

Thus nearly 12½ per cent. of the articles were proprietary. Nearly 10½ per cent. were unofficinal, or over 31 per cent., or one-third of the different kinds of articles called for were not recognized by the Pharmacopœia.

There are 997 different articles in the U. S. Pharmacopœia. 704, or nearly 70 per cent. of these were not ordered at all, though it must be remembered that many of the 293 articles prescribed are compounds or manufactured from something else, and that many of the 704 not ordered are crude drugs that enter into the composition of the 293, or from which these are made.

The Result of Swallowing a Fork.—Dr. William Wilson, writing to the *Lancet* of May 28, 1887, from Florence, Italy, reports the following interesting case:

Cipriani, to whom you referred in a recent number, while imitating the exploits of a juggler in swallowing a fork, some sixteen years ago, allowed it to pass into his œsophagus beyond his control. After various attempts at extraction, made by himself, his friends, and his wife, he was, on the following day, transferred to the Ospedale de Santa Maria Nuova, where also all efforts at removal were unavailing. Several ingenious instruments were invented for the purpose, but failed. He remained in the hospital for five weeks, suffering more or less inconvenience, moral as well as physical, for the public were divided in opinion, some proclaiming him only a fool, others an imposter. A year or so afterward, having produced severe pain, hemorrhage, and other untoward symptoms, it was ascertained that the fork had effected its exit from the stomach, and passed into the intestines, accompanied with a relief to the more urgent

phenomena; motion, however, occasioned severe suffering. He now wandered from place to place, a subject of interest to some, of ridicule to others, till three or four weeks ago he was attacked by acute pleurisy of the right side, terminating in effusion, and was admitted into the Ospedale di San Giovanni di Dio. Recovering from this, attention was again directed to "the fork," which was discovered in the right iliac fossa, pointing obliquely upward to the left side. It was evidently fixed in this situation, for palpation effected no change in its position, and considerable enlargement could be detected in the immediate neighborhood. After long hesitation, he consented to an operation, which was performed by the distinguished surgeon Professor Rosati, aided by his skilful assistant, Dr. Catani. An incision was made extending from an inch and a half below the umbilicus perpendicularly down to the pubes, and after considerable difficulty the fork was extracted from the ascending colon, the blunt end pointing upward. There had been long and constant inflammation, as was proved by the great thickening of the bowel, adjacent tissues, and the firm adhesion of the colon to the abdominal parietes. The bowel was opened, the edges secured to the abdominal integuments, and the wound dressed in the usual way. The fork measured twenty-two centimetres, and presented but little erosion; for though the plating had disappeared, the extremities retained their original defined outlines. The time could not be calculated which it had taken in reaching its ultimate destination, but probably many years, judging from the condition of the surrounding textures. The patient bore the operation well, and was very anxious to secure possession of the fork as conclusive evidence against his detractors. There has been no fever or unfavorable symptom, and the wound is nearly healed, there remaining only a small fistulous opening communicating with the intestine.

CREMATION BY THE BOURRY SYSTEM.—The cremation society at Zurich, Switzerland, one of the best organized associations in the world, has adopted the Bourry system, which is described as follows: "Like Siemens, Mr. Bourry allows only heated air to communicate with the body. In both systems the corpse burns directly; no flame is to be seen singeing the body, but it burns itself by the abundance of hot oxygen which surrounds it. Bourry uses carbonic acid gas, prepared in a coke regenerator, for heating the crematorium. During the process of cremation he uses, mainly, chimney gases for heating the air before it touches the corpse, which allows a more economical use of the heat. It is of great advantage that the chimney needs to be thirty-five feet high from the base of the cellar, so that it is fully covered up by the building. The ashes fall, without being touched, by an almost automatically working apparatus into the urn. The dissolution of the body does not take place in the dark, unseen and uncontrolled, but the whole action is clear and open. Bourry and Venini place the crematorium, which has the shape of a sarcophagus, and which can be approached from all sides, in the midst of the hall in which the service is to take place. There is a little window on the back of the sarcophagus through which one can see the process of cremation, which is completed within one to one and one-half hours, without smell or smoke. The process is solemn and beautiful, and avoids every unæsthetic manipulation."—*The Sanitary News*, May 14, 1887.

WHAT HANDWRITING SHOULD CHILDREN BE TAUGHT?—Schubert, of Neuremberg, has made a careful study of various kinds of script, and the bearing which the use of each has upon the hygiene of the eyes among children, and the following are his conclusions:

As a practical conclusion to be drawn from his observations, Schubert lays down the rule that all children should be taught a perpendicular handwriting. Even if the erect median position of copy book be not actually better than the oblique median, still the teacher cannot tell when inspecting writing done at home what absurd position may have been adopted in writing it, if the child is permitted to write anything but perpendicular letters. These latter can only be executed in the erect median position. It may be possible for adults to write more rapidly a slanting than a perpendicular hand, but children are not required to write rapidly, but in a manner that does not tend to deform their vertebral columns or their eyes. In many countries now-a-days, and in times past, perpendicular handwriting alone obtains, and Schubert appends a series of fac similes of German handwriting in every century from the 8th to the 18th inclusive. From this it is seen that slanting letters were not adopted to any extent until the 17th century.—*Ophthalmic Review*, May, 1887.

SPONTANEOUS PURIFICATION OF RIVER WATER.—It is well known that rivers which in flowing through towns become charged with various organic substances, by degrees get rid of these impurities as they flow to a considerable distance. This can only be due to the oxidation of these organic matters, and M. Emich, who has studied the causes of this oxidation, arrives at the following conclusions. If pure water be left undisturbed, and in contact with atmospheric air, it is purified in the same time as it would be by being shaken in contact with the air. Ozone is not perceptibly quicker in action than ordinary air; if impure water be boiled and left in contact only with air deprived of germs by filtration through cotton, the organic matters will remain in it. If the deposit precipitated by water kept in contact with the air be mixed with water previously boiled, organic matter quickly disappears. The process of oxidation consists in the transformation of ammonia and its compounds into nitric acid and nitrogen. These facts show that the spontaneous purification of water containing germs results from the development of organisms, which act in the same way as the nitric ferment discovered by Schloesing.—*British Medical Journal*, May 7, 1887.

NUTRITIVE VALUE OF MUSHROOMS.—The prevalent idea (at least in Europe) that mushrooms are a food of no mean value, is not supported by facts. C. TH. MOERNER (*Schweitz. Wochenschr.*) has investigated the subject, and finds that only forty-one per cent. of the total amount of nitrogen may be considered as assimilable, and the nitrogen does not amount to more than about six per cent. of the dried mushrooms. He calculates, from the above data, that ten and a half avoirdupois ounces of *Agaricus campestris* are equal in nutritive value to only one average-sized hen's-egg; of

Polyporus ovinus, we need no less than four pounds; nine pounds of *Agaricus campestris* are equal to only one pound of beef; while of *Polyporus ovinus* it requires sixty-seven pounds.—*Popular Science News*, May, 1887.

DIMINUTION IN THE DEATH-RATE OF CONTINENTAL COUNTRIES.—At a recent meeting of the Society of International Statisticans, held at Rome, M. VACHER showed a diminution in the world's death-rate, as shown by the statistics of different lands. Taking France as an example, a mortality rate of 34 per cent. in 1770 became 24 per cent. in 1880; in Sweden 28 per cent. in 1760 was reduced to 17 per cent. in 1880.

M. BORDIO reported a steadily diminishing death-rate for Italy, since 1870: the result of improved drainage of marsh lands, and advances in national hygiene.

NOTES AND QUERIES.

MR. ERSKINE'S LINES ON DR. PHYSICK.

In the year 1792 Dr. Philip Syng Physick, of Philadelphia, received his degree of M.D. at Edinburgh. Upon its announcement Mr. William Erskine, the lawyer, afterward Lord Kinneder, wrote the following verses. In 1834 they appeared in "The Court of Sessions Garland," of Edinburgh, a work limited to one hundred and fifty copies

Sing Physick! sing physic! for Philip Syng Physick
Is dubbed Dr. Phil for his wonderful skill;
Each sick phiz he'll physic, he'll cure every phthisic,
Their lips fill with Philips with potion and pill

If music, as Plato does stoutly maintain,
In every disease be a sovereign thing
For calming the spirits and cooling the brain,
Be sure, Dr. Phil, when you physic, to sing.

Do! Physick! the college permits thee to work
In curing diseases the greatest of curses;
Syng! Dance! then with joy when thou think'st at one jerk,
Physick can empty both stomach and purses

What a fillip to physic if Philip Syng Physick
His skill in His quill to support him shall bring,
Of fever and phthisic, each master and miss sick,
Of Philip Syng Physick the praises shall sing.

Each grip in the science of physic to fill up,
Old Plochlus young Philip Syng Physick bestows;
The potion and pill of Phil still shall we swill up,
And Syng shall be sung at the close of the dose.

The physic of Philip sel sweetly to swill up,
Health, joy, and delight among mortals shall bring,
With pap and with praise, then, still Philip we'll fill up,
And Loud Io Paans to Syng ever sing.

O, Death! Since Phil physics thy triumphs are past
And broken thy dart is and blunt is thy sting;
Phil shall fill us with physic while Physick doth last,
And while Syng Physick physics, we'll Syng ever sing.

To each creature his own is the dearest and sweetest,
My host loves old stingo, and Iopas the bee;
Then Physick with physic sel Philip shall fill up,
And sung by Syng Philip philippics shall be.

When Philip's great son, as old chroniclers sing,
Fell sick, to great Philip[1] for physic he flung;
Then Philip with physic so fillipped the king
That physic and Phil by Timotheus were sung.

Now broke are Phil's pill box and Timotheus's lyre,
Let fame to my hero their blazonments bring,
Like Philip's great son he can bleed—in the sire,
Can physic like Philip, like Timothy sing.

[1] Philip was the name of Alexander the Great's physician.

Syng Physick for fees seeks the sick man to physic,
But unsought hopes the fee of his physic and skill,
To ne'er let Phil Physick of physic the fee seek,
Nor the sick man be fee sick of physic and Phil.

Let physic sing Philip, for Philip Syng Physick
From plain Philip Physick is dubbed Dr. Phil,
Sing Syng then, each patient, while Philip shall physic,
And Physick shall fillip with potion and pill.

That Apollo the god is of physic and song,
Each schoolboy, I think, will fully readily hollo;
Then since to his name the same arts do belong,
Be Philip Syng Physick our Magnus Apollo.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JUNE 28 TO JULY 2, 1887.

MCKEE, J. C., *Major and Surgeon.*—Granted three days' leave.—*S. O. 149, A. G. O.*, June 29, 1887.

BEALL, GEORGE T., *Captain and Medical Storekeeper.*—Granted four months' leave of absence.—*S. O. 150, A. G. O.*, June 30, 1887.

CHERBONNIER, A. V., *Captain and Medical Storekeeper.*—Directed to take charge of office and perform the duties of Acting Assistant Medical Purveyor, in St. Louis, Mo., during absence on leave of Captain George T. Beall, Medical Storekeeper, now performing those duties.—*S. O. 150, A. G. O.*, June 30, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 2, 1887.

DEANE, C. W., *Passed Assistant Surgeon.*—Ordered to the Naval Rendezvous, San Francisco, Cal.

HARRIS, H. N. T., *Assistant Surgeon.*—Ordered to the Naval Hospital, Mare Island, Cal.

GORGAS, A. C., *Medical Director.*—Remain on present duty until December 31, 1887.

CLEBORNE, C. J., *Medical Inspector.*—Remain on present duty until December 31, 1887.

MACKEY, BENJAMIN F., *Surgeon.*—Remain on present duty until December 31, 1887.

BROWNE, J. MILLS, *Medical Director.*—Will remain on present duty as member of Retiring Board, until June 30, 1888.

DEAN, RICHARD C., *Medical Director.*—Will remain on present duty as member of Retiring Board, until June 30, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING JULY 2, 1887.

ARMSTRONG, S. T., *Passed Assistant Surgeon*—Relieved from duty at Marine Hospital, Memphis, Tenn.; ordered to Marine Hospital, New York, N. Y., June 27, 1887.

PECKHAM, C. T., *Passed Assistant Surgeon.*—Relieved from duty at Marine Hospital, Wilmington, N. C.; ordered to Marine Hospital, Memphis, Tenn., June 27, 1887.

GLENNAN, A. A., *Passed Assistant Surgeon.*—Ordered to Revenue Cutter "Crawford," for temporary duty, June 30, 1887.

BROOKS, S. S., *Assistant Surgeon.*—Ordered to examination for promotion, June 27, 1887. Relieved from duty at Evansville, Ind.; ordered to Marine Hospital, at Wilmington, N. C., June 27, 1887.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

CHOPART'S AMPUTATION.

An Extract from "The Address in Surgery" before The Medical Society of the State of Pennsylvania, June 29, 1887.

BY J. B. MURDOCH, M.D.,

OF PITTSBURG, PA.

ATTENDING SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL, PROFESSOR OF CLINICAL SURGERY IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE, ETC.

THIS operation is made at what is called the mediotarsal joint, between the scaphoid and cuboid bones in front and the astragalus and os calcis behind. The joint is situated about midway between the tarso-metatarsal articulation in front and the ankle-joint behind. These two being the points at which Hey's and Syme's amputations are respectively performed, the field for the performance of a Chopart is exceedingly limited, and the opportunities must necessarily be very few for its performance as compared with either of the others.

It is, however, an admirable operation in cases to which it is suited, and should be selected in those cases in which the disease or injury extends too far back to permit of the performance of a Hey's amputation, and still there is sufficient tissue left upon the sole of the foot out of which a plantar flap can be secured to cover the face of the astragalus and os calcis.

"Although an effort," says Hancock, in his lectures on the anatomy and surgery of the human foot, "has been made by Velpeau and others to fix the date for the first performance of Chopart's operation in the year 1746, and to give the credit to Hecquet, of Abbeville, for doing the operation, I have no doubt that the honor of originality has been justly awarded to Chopart. Boyer, a great admirer and supporter of Chopart, who speaks with the authority of personal knowledge, not only fixes the date as the 21st of August, 1791, but adds that "Chopart was so modest and disapproved so much of the practice, so prevalent nowadays, of proclaiming one's name in the journals, that it was only at his (Boyer's) express solicitation that he consented to his case appearing in Fourcroy's journal," which it did in 1792. In this case Chopart made two incisions, one on each side of the foot, extending forward from the astragalo-scaphoid and calcaneo-cuboid articulations. A transverse incision on the dorsum of the foot joined these two at their anterior extremities. The flap reflected back, Chopart cut through the extensor tendons and the dorsal ligaments. He next luxated the bones by depressing the front of the foot; and carrying his knife behind and below the bones, he cut from behind forward through the soft parts of the sole an inferior flap a little longer than the upper one. Secondary hemorrhage took place upon two occasions, but in spite of this the patient recovered and left the hospital on the 9th of November, or eleven weeks after the operation, able to walk upon the foot as well as on the other."

Probably few operations in the whole domain of surgery have had so many objections urged against them as the one now under consideration. Some of the objections are trivial, but one of great force is that the anterior tendinous attachments being necessarily cut off the gastrocnemius and soleus muscles draw the heel upward, in consequence of which the cicatrix becomes exposed to pressure in walking, and hence is liable to undergo ulceration. All surgeons of much experience have seen cases of this kind. It has been my fortune to witness two cases in which amputation at the ankle-joint was performed to remedy this difficulty.

Many good surgeons have expressed themselves as opposed to this operation. On the other hand equally good, if not better, authority can be quoted in favor of its performance. Mr. Syme was in the habit of performing it in preference to his own operation in all cases to which it was applicable. He never designed his own operation as a substitute for that of Chopart. Some time after he had devised the operation at the ankle-joint he said, "The operation of Chopart, which leaves only the astragalus and os calcis, is the most valuable of all the partial amputations, as it commands the largest portion of the foot requiring removal for disease or injury, and at the same time preserves a support for the patient not less useful than that which is afforded by the whole of the tarsus. Its introduction was long opposed on the ground that the extensor muscles of the ankle acting through the tendo-Achillis, when no longer antagonized, would draw up the heel and point the cicatrix to the ground. I performed this operation in 1829, and have frequently done so since with the most satisfactory result, no inconvenience having ever been experienced from the source just mentioned, as the cut extremities of the tendons on the forepart of the joint speedily acquired new attachments, enabling them to counteract the extensive power."

It is no wonder, therefore, that we see the greatest diversity of practice in this regard. In our great iron-mills and at our railroad centres so many feet are crushed under heavy weights, that amputation of the foot at some point is one of the most frequent operations the surgeon is called upon to perform, and it is of the utmost importance that all questions pertaining to the subject should be definitely settled. In this connection the following case is of interest:

CASE.—Robert G., mulatto, twenty-two years old, was admitted to the Western Pennsylvania Hospital, January 31, 1884. Patient had been found lying near the track of the Lake Erie Railroad twenty miles from the city. While in a state of intoxication he became sleepy and had lain down beside the track. The night was intensely cold, and it is presumed that he was out all night. When he was brought to the hospital it was found that the anterior portions of both feet were frozen.

A line of demarcation soon formed upon both feet. On February 6th (one week from admission) the question of amputation was considered. Quite a number of surgeons were present besides the resident physicians of the hospital, and while there was a unanimity of opinion as to the propriety of amputation, there was a difference as to the point at which the amputation should be made. The lines of demarcation were oblique; they were the same upon both feet, the tissues being destroyed to a greater extent upon the dorsal than upon the plantar surfaces. Syme's and Chopart's operations were fully considered. Those who advocated the doing of Syme's amputation asserted that the result in Chopart's operation was always doubtful, and that especially in a case like this, where both feet were implicated, it should not be attempted. After a full consideration of the subject it seemed to me that this was a case especially favorable for Chopart's operation. Good flaps could be secured from the soles of the feet, and I felt confident, from the experience which I had had in previous cases, that I would be able to prevent the pulling up of the heel.

Chopart's amputation was accordingly performed upon both of the feet; there being no skin on the dorsal surface of either foot out of which to form flaps, the medio-tarsal joint was opened in both cases directly from above, and a sufficient flap obtained from the plantar surface of each foot to cover the bones. The arteries were twisted, the wounds held together with silver wire sutures and adhesive plaster and a dressing of dry oakum applied. To prevent the drawing up of the heels, a subcutaneous tenotomy was performed upon both tendones-Achillis and a sole-leather splint accurately moulded to the back and sides of each leg, extending down upon the heels. In this manner the ankle-joints were kept well flexed. The dressings were not disturbed until the fourth day after the operation, when the wounds were found to have united through

their whole extent, with the exception of about half an inch on the right foot. During the time the patient remained in bed the heels were kept well extended by the sole-leather splints. He was able to get upon crutches at the end of four weeks, and was discharged from the hospital April 2d, sixty-three days from the date of admission. I did not see this patient until June 1, 1887, three and one-half years from the date of the amputations. The result did not disappoint me. After his dismissal from the hospital the patient informed me he continued to wear the splints which had been moulded to his legs at the time of the operation for three or four months, when he discarded them, and has since worn nothing but a pair of ordinary leather gaiters laced in front. He keeps the front of his shoes stuffed with cotton or some other soft material. He is engaged as a cook in a boarding-house; he is able to walk to his home, a distance of four long city blocks; he frequently walks down town to the post-office and back, a distance of two miles, with no other assistance than an ordinary cane. He is able to flex and extend both ankle-joints with perfect ease and to their full extent. He asserts that his feet give him no pain, and that he would much prefer to have them as they are than to have them off at the ankles. In this opinion all who have seen him walk must agree, unless, indeed, it would be the artificial limb manufacturer. I show you these plaster casts taken of his limbs a few days ago; also these woodcuts taken from photographs. The fact that the patient is a negro will explain the prominence of the heels.

This case is of interest from the fact that the operation of Chopart is an exceedingly rare one as compared with the other amputations of the foot, and it is of importance for the purpose of settling conflicting opinions in relation to it. It is also an important case from the fact that it is the only case, so far as I have been able to learn, where the operation has been done upon *both of the feet*.

The fact that this patient is able to walk with no other assistance than an ordinary cane, and has been doing so for more than three years, speaks volumes in favor of the operation. It shows the value of the stump as a support for the weight of the body and as a means of locomotion more clearly than could be shown by many cases where the operation was done upon only one foot. This is a very severe test of the operation. When one foot only is lost a patient is able to help it by throwing most, if not all, of his weight upon the other foot, but when both are gone, each foot must bear the brunt, and do its share of the labor. For this reason it is rare to see a man who has lost both of his limbs walking without the aid of a crutch (artificial limb manufacturers to the contrary notwithstanding), and when one is found who does so, he usually uses two canes, and, in order to keep his balance, extends his arms to their full extent, and walks in a shuffling, ambling manner, much different from the manner in which my patient walks.

I could state other cases of Chopart's amputation which have come under my observation, where the result was much better than it is possible for any of Syme's amputation to be.

I know a gentleman in Pittsburg whom I meet daily on the street; he is an active young man of twenty-two years of age. Nine years ago his right foot was traversed by a car wheel, crushing the foot up to the instep. For this injury his foot was at once amputated by the method of Chopart. Few who meet him on the streets suspect that there is anything the matter with his foot. There is a spring and elasticity to his tread which

I have never seen in any one who has suffered a Syme's amputation, and which I believe it impossible to obtain by any artificial contrivance in a case where the ankle-joint is lost. This man is a salesman in one of our largest and most busy retail stores; he is on his feet all day actively engaged in waiting upon customers; he walks to and from his home in the suburbs of Allegheny, a distance of two miles, from his store; he is a good dancer, and few of his companions can equal him as a pedestrian. It is proper to state that this man wears an artificial appliance upon his foot.

From my experience in these and other cases I feel justified in recommending Chopart's amputation in all cases to which it is applicable. It is not pretended that it can take the place of a Syme's amputation. Where there is not a sufficiency of healthy tissue to obtain a good flap from the sole of the foot, the operation should never be attempted. The flap upon which the patient is expected to walk should never be made from the tissues upon the dorsum of the foot. The skin over the instep cannot be made to bear the pressure of the weight of the body without ulcerating and causing pain. The dorsal flap should, therefore, always be short. Another reason for making a short dorsal flap, or no dorsal flap at all, is, that by so doing the tendon of the tibialicus anticus muscle and the tendons of the other flexor muscles of the foot are cut short, and for this reason when they become attached in the cicatrix are the more likely to keep the foot flexed, and thereby counteract the extending force of the gastrocnemius and soleus muscles. When, however, a sufficient amount of good flap can be obtained from the sole of the foot, no surgeon should do a Syme's in preference to a Chopart's amputation.

Many of our best surgeons are in favor of the operation. They do it in all suitable cases. It is fair to conclude that those who fail should charge their failure to the fact that they have done the operation in cases to which it was not applicable, or to a want of proper management in the after-treatment of the case. It is in the art of surgery as in other arts, those who fail in methods where others succeed should charge the failure not to the method, but to themselves. In cases where there is a sufficiency of plantar flap and the ankle-joint is kept well flexed during the after-treatment of the case, there will be no failure. To accomplish this it is prudent to divide the tendo Achillis subcutaneously at the time of the operation.

Mr. Delagarde, of Exeter, England, advises that in sewing up the flap after the operation the tendon of the tibialicus anticus muscle should be transfixed by one of the sutures. He relates three consecutive cases in which he resorted to this procedure which were entirely successful. He asserts that as the wound healed the tendon became firmly attached to the cicatrix. This seems to me to be an excellent suggestion, and is one which I shall in future adopt.

With regard to the mortality after Chopart's amputation, the statistics would indicate that they are about the same as after Syme's amputation, viz., seven per cent. But Chopart's is an operation so seldom resorted to, and the statistics have been so imperfectly recorded, that they are of little value. I think it is fair to infer, on general principles, that the part removed in a Chopart's amputation being not more than half of that removed by a Syme's, that the danger to life cannot be as great.

In conclusion, let me say that the principle for which I have contended is the same as that which has governed surgeons for hundreds of years in their amputations upon the arm. It is the same principle which Mr. Syme established fifty years ago for the leg, viz., *that amputations should be made as far from the trunk as possible*. This principle is as good for the foot as it is for the arm or leg, and, therefore, we say that the surgeon who performs a Syme's amputation when he might do a Chopart's, or a Chopart's where a Hey's would answer, increases the risks and unnecessarily mutilates his patient.

STRICTURE OF THE URETHRA IN WOMEN.[1]

BY ELY VAN DE WARKER, M.D.,
OF SYRACUSE, N. Y.

IN view of the great frequency of diseases of the urinary organs in women, and in consequence the very thorough study that has been given them, it is extraordinary that so little attention has been directed to stricture of the urethra. All the great systematic writers, who are unquestionably thorough in all else, are silent, or treat worse than silently, a matter that I have reason to believe to be of great importance.

As instances of this, notice the following: Thomas, in his fifth edition, does not mention the subject. Emmet says that it is rare, except as the result of violence. Among older English writers, Churchill, who had such a wide experience, and could relate it so graphically, says, "My own experience does not qualify me to speak as to the frequency of organic stricture of the female; it cannot be very common, or I should have met with it. But I have met with two cases which I suppose to be spasmodic stricture;" and which cases he relates, and which were evidently cases of hysterical retention. West does not mention it, neither does McClintock; Sir C. M. Clarke gives it no place. Graily Hewitt says it is very rare compared to the other sex, and dismisses the subject in eight lines. Barnes ignores the matter, and Tait finds it unworthy of mention. The later French authors do not give it any consideration, so far as I have examined. The elaborate and painstaking German authors give it equally scant treatment. Beigel makes no mention of the subject; and Winckel, in a special treatise on the "Urinary Organs of Women," in the *Handbuch der Frauenkrankheiten*, gives it but a very scant space. Hart and Barbour do not mention the subject, except as atresia due to fistula. Skene, in his work on the *Diseases of the Bladder and Urethra in Women*, says that it occurs often enough to demand attention, and claims for it certain consideration due to its peculiarities in women. Mainly, its causes are the same in both sexes; the deposit of inflammatory products beneath the mucous membrane, which by gradual contraction constrict the canal. There

[1] Read before the Medical Association of Central New York.

is nothing here that differs in either sex, but he says it "may be produced by bands of scar tissue formed in the anterior vaginal wall and stretching across the urethra." Vesico-vaginal fistula may also cause it, and which we may call the stricture of habit. In the next sentence he makes what I believe to be an error. "The form of stricture that will most frequently come under your observation," he says, "will be a contraction of the meatus urinarius, produced in many cases by the too liberal use of caustics in the treatment of abnormal growths at the lower end of the urethra, or from vulvitis." Now if there is any point at which stricture in the sexes differ, it is the extreme frequency with which we find contraction of the meatus in the male and its rarity at this point in the female. Abnormal growths of the orifice of the urinary passage in women are exceedingly common, and when present, with very rare exceptions, they cause dilatation of the opening, which will not be more than compensated for by the action of caustics; but I believe that caustics are as rare in the treatment of these growths at the meatus as is stricture at this point in women. I have never seen a vulvitis treated by caustics to such an extent as to cause a slough, and without that, stricture would not result.

The subject upon which the greatest importance should be placed is given very doubtful treatment by Dr. Skene. Concerning the diagnosis, the directions are to explore the passage with the sound, using one so large that it will not pass the stricture, and thus locate it, and then by using a sound that will pass through it the extent of the obstruction can be known. If a writer upon male stricture were to direct such a method of exploring the passage, there would be very few strictures of large calibre, as Otis calls them, that we would ever know much about.

I have given extra space to Dr. Skene's very excellent treatise, because it is the only one of importance in our language, and if such an author treats a subject lightly, or in a way to prolong the period of error, we may dismiss any further consideration of those who are regarded as authority. Among the special journals the subject has been given more attention than in the text-books, and it is not an unusual thing to find the report of cases of stricture of the female urethra, and particularly has this been true for the last few months, with the result of a gradual awakening to the fact that an important pathological condition has been nearly overlooked.

The systematic gynecological writers are all wrong in their estimate of the importance and frequency of stricture of the female urethra. As the result of my own individual experience, I believe that it is as frequent as a like condition in the male, and the consequences to one sex are as serious as to the other. If this be true, it is an important matter, and each individual experience ought to be made available to correct the omission.

Now there was a time within the memory of many among us when it may have been said that in an exact and scientific way we knew very little about stricture of the male urethra; and yet, concerning this, important and careful instruction had been given for generations. There came, however, with the use of instruments of precision, a period of more exact examination, which not only gave us more perfect but a far wider range of knowledge. By these means could we study the pathological condition of the urethra within the living subject, but an abnormal state was all but discovered, and its morbid outcome given its due value, for, previous to this, strictures of large calibre were, if known, given no practical importance. Up to this period the general surgeon gave about the same instruction concerning the diagnosis of stricture of the male urethra that Dr. Skene has given in the same condition of the female passage. It cannot be disputed that, so far as stricture in women is known and treated, it stands to day where the surgery of the male urethra did half a generation ago. I date the knowledge of stricture in the male, of large and small calibre, their number, location, and extent, their consistency and dilatability, together with the calibre of the passage yet in a normal condition, to the invention and general use of the exploratory bulbs and urethrometer.

If we trust in urethral exploration in women to the sound, we simply learn that we have to deal with a narrowed passage, and we overlook strictures of large calibre entirely; whereas, if we explore with the bulbs, we learn all that the sound can reveal, but also the extent, number, and location of the constricted points, their firmness and dilatability, and the differential diameter of each.

Dr. Skene, in common with the very few writers who have given any description of urethral stricture in women, appears to derive his standard of comparison from stricture in the other sex. To a certain extent no comparison is possible. Except as the result of traumatism, the impervious urethra, or exceedingly narrow stricture, is not met with in women, but this form is quite common in men. Further, a narrowing in men that will cause but slight diminution in the current of urine, never retention, and but rarely dysuria, will result in all these symptoms in women. I believe this to be the true distinction to make between the sexes in the pathology and symptoms of stricture. Of course, women are exposed to all the etiological conditions that men are, plus a few others, incidental to their sex, but these in no way contribute to what may be regarded as sexual differences in results. From whatever cause, retention, incontinence, and dysuria are symptoms much more frequently met with in women than in men, and in consequence slighter pathological changes will cause more active disturbance in the former. If strictures of large calibre have the pathological importance in men that such an accurate observer as Dr. F. N. Otis assigns to them—and there can be no doubt of the truth of his observations—strictures of like character have still more serious import in women.

It is not necessary to reason any further from analogy. I am able to appeal to facts to establish the truth of my position. A long established method of treating dysuria in women has been by forcible dilatation of the urethra, an operation usually made with the finger of the operator. I had so treated

these cases of painful urination many times; sometimes with success, at other times with failure; but it appeared difficult to explain the contradiction in result. I have now learned that when I succeeded in relieving my patient I had to deal with a stricture of large calibre—in other words, I had treated a stricture by what, in the surgery of the male urethra, we would call divulsion. Since I began habitually to explore the female urethra with the bulbs in all cases of bladder disturbance, I have never made the operation of forcible dilatation, except in those cases in which a large sized bulb, say Nos. 24 to 27 F., has demonstrated the presence of constricting bands, with the result of making the operation much less frequently but with more uniform success. In forcing the finger into the urethra I have frequently felt the narrow constricting bands, but without really understanding their nature until I had studied the condition of the passage with the Otis bulbs. It is impossible to detect strictures of this size by the sound, as resistance is at every point alike; and from the size of the sound that you are able to pass, it does not appear that any stricture is possible. Free as was the opening of the urinary passage, the widely dilatable constricting bands were sufficient to keep up a constant fret of the mucous membrane. This, I believe, constitutes a sexual trait in the different reaction of stricture of this character in the sexes; that which will cause frequent and painful urination in women, and greatly dispose to spasmodic retention, simply, as a rule, causes an intractable urethral catarrh in men.

It is remarkable how sensitive the bulbs are in detecting and locating strictures of wide lumen. Sometimes the constrictions are arranged in series, and a No. 24 to 27 bulb will slip along in a series of jerks that offer but the slightest resistance to the hand; but more usually one or two of these bands are found located at the middle or upper portion of the urethra. The lumen of the normal female urethra is not the same throughout its length. It is contracted toward the meatus, expanded in the middle portion, and narrows again as it approaches the bladder. The use of the urethrometer proves this. One must not, therefore, allow error to occur from the introduction of too large a bulb, and which would move with more freedom at one portion of the urethra than another. The sensation of meeting and passing one of these bands is so characteristic and unmistakable that there is but little danger of error.

I am not prepared to give an opinion on the etiological relations of these large strictures. They differ in one important particular from obstructions of the same diameter in the male. In women they occupy but a small space longitudinally of the passage, while in men a half to one inch is sometimes involved. All the symptoms evoked by strictures of more contracted diameters are observed in those I have been describing.

In those cases in which the lumen of the passage is greatly reduced, I know of no way to differentiate them by the degree of functional disturbance from the first variety. I have made it a part of the routine examination of a patient to explore the urethra by the Otis bulbs, and as much a matter of course as examination by bimanual palpation or examination by the rectum. This I have practised for about three years, with the result of inducing me to reject the usual teachings of the systematic authors, and to believe that stricture of the female urethra is a frequent condition. Symptoms of functional disturbance due to stricture have their periods of exacerbation and intermission, so that the patient will give a history of difficult or painful micturition with intervals of relief.

In strictures of small dimensions, if the obstruction is sufficient to diminish the stream, this symptom, of course, persists, but even here it is subject to varying degrees of intensity, amounting occasionally to retention, while it is possible to introduce a fair sized catheter. I have observed the same symptom in the male, and in which the retention could be relieved by a No. 20 F. catheter. In women it is not safe to regard every case of urine retention as hysterical until, after a urethral examination by the bulbs, the passage is shown to be free from strictures, large or small.

The most contracted urethra I have met with offered firm obstruction to a No. 16 F. bulb. It was situated about half an inch from the meatus. She had complained of urinary difficulties for about eight years, and been treated for urethritis and cystitis and disease of the kidneys by a great variety of physicians. She was forty-seven years old, and about ten years before had had gonorrhœa, and to which I attributed the stricture.

I never saw but one case of contraction at the meatus. The subject was sixty-two years old, the mother of several children, and had suffered quite a number of years from difficult and painful micturition. A No. 19 bulb could be passed with difficulty through the meatus; another stricture slightly larger was found half an inch further up the passage. I divided the meatus, as dilatation at this point was exquisitely painful, even after using cocaine. The division was made upward—just the reverse of the direction in which it is made in the male. From the thickened and inverted prepuce, the hypertrophied right nympha, with its hardened and corrugated surface, and the general pigmentation of both nymphæ, I suspected long continued masturbation, although the social position of the patient forbade any questioning upon the subject.

I do not propose to take up your time with illustrative cases, and have alluded to these only as possible proof that like causes operate in both sexes. Senile stricture and stricture at the vesical neck are met with, and are extremely unsatisfactory to treat.

As I have consumed my allotted time, I can only briefly notice the treatment. Of course, the bulbs are not used for the purpose of dilatation. I make use of graduated steel sounds, the same that I used when in general surgical practice to treat male stricture. The action is twofold—to dilate and to cause gradual absorption of the constricting exudate. In strictures of large size, forcible dilatation or divulsion may be used: but I doubt the utility of this method in rigid strictures of small dimensions, as I

believe it would be found necessary to supplement the operation by the use of the sound to prevent contraction. The treatment, made two or three times a week, extends over a considerable length of time—from two to three months: but the relief given to the patient early by the use of the sounds is very satisfactory. As dilatation of the urethra is no more important than the absorption caused by their use, the latter implies a more or less prolonged treatment.

I believe any one can verify my position upon this subject by the habitual examination of the urethra with the exploratory bulbs in every case of pelvic disease that presents itself for treatment. The usual practice is not to explore the urethra, except when urinary symptoms are present, and then either by the sound or by some form of urethral speculum. My own experience is that one may learn more by the thorough way in which you can *feel* the conditions of the urethra by a properly selected bulb than by seeing. Speculum or endoscopic examination of the female urethra is a very unsatisfactory method compared to the touch. Here, as in other pelvic diseases of women, the gynecologist ought to make his diagnosis by the touch. As women are extremely sensitive in the urethra, cocaine should be used both in examination and treatment. In the examination the solution ought to be employed of full strength —5 per cent.—as the passage of the bulb is much more painful than that of the sound.

BASE-BALL PITCHER'S ARM.

POINTS IN ITS ANATOMY, PHYSIOLOGY, PATHOLOGY, SYMPTOMATOLOGY, AND TREATMENT, TOGETHER WITH SUGGESTIONS AS TO ITS PROPHYLAXIS.

BY A. H. P. LEUF, M.D.,
OF PHILADELPHIA

WHILE we have regularly made the acquaintance of the "tennis arm," "bicyclist's prostate," and other allied conditions, only a small proportion of the profession know anything about the disability of base-ball pitchers. As a rule, only those of us who take an interest in the great national game have heard from time to time of the total disability from overwork of some of the best pitchers.

The importance of a knowledge of this class of ailments can readily be appreciated from a monetary standpoint when it is remembered that good pitchers have salaries ranging from two thousand to four thousand dollars for a season's work of six or seven months, with but from one to three working days in the week.

For the benefit of those who know little or nothing of the game, and what is required of the pitcher, it would be well to make a few explanations. The average time occupied in a single good game of ball is from one and a half to two hours. During this time the pitcher takes his stand nine times in what is technically known as "the box," to "pitch" the ball toward the batsman. It is fair to say that he averages about twenty "pitches" each time he is in the box. This would make about one hundred and eighty pitches in each game. Sometimes the number is much greater and sometimes much less. The ball is delivered with all possible speed, so that the batsman has as little time to deliberate and gauge the ball as possible; the ball has been pitched from the box to the plate, a distance of fifty feet, in seven-eighths of a second. This work alone would be very trying, as it is extremely violent, the ball being thrown with all the strength of the player's whole body. Moreover, the ball is deflected from the usually vertical curve in any direction before it reaches the batsman.

It is the business of the pitcher to deliver the ball with the greatest possible, or a modified, speed, as his judgment directs, and coupled with this he so handles the ball before allowing it to leave him, that it is caused to deviate to the right ("in-curve") or left ("out-curve"), as the case may be, after it has taken its course in a certain direction. Not only does he do this, but he may also cause the sphere to make a sudden and unexpected ascent ("up-curve") or descent ("down-curve"). Any combination of these curves is possible, as up and out, down and out, up and in, and down and in.

I shall now attempt to explain more in detail the method of producing these curves, so that the etiology of "pitcher's arm" may be understood.

In the act of delivering the "in-curve" or "in-shoot"—so called because it turns suddenly toward the pitcher's right, in toward the batsman—the arm is swung forward at full length, the body also taking part thoroughly in the effort; every muscle is strained to give the ball speed. Just before it leaves the hand, the forearm and hand are sharply drawn across the chest, and the hand flexed quickly on the wrist with a sudden jerk or snap, and the ball allowed to roll off the tips of the index and median fingers. This imparts to the ball a rotary motion forward and from left to right.

In the position for pitching the "out-curve" the arm is also swung at full length, either above or below the shoulder. Then, with a short, quick motion, the hand is quickly flexed and adducted, and the elbow drawn backward and outward, while the ball is allowed to roll off the radial side of the index finger. This imparts to it a rotary motion forward, and from right to left.

In the delivery of the down curve, or drop ball, so known because while in the act of yielding to gravitation in the ordinary manner, it suddenly takes a sharp turn down, and falls to the ground several feet shorter than it would have done without the special twist imparted to it for this purpose. The arm is swung back with full force, and brought up over the head, or on a level with the ear, with the forearm a little flexed. The greatest force is now exerted in bringing the hand and arm quickly downward and forward, when, just before the ball leaves the pitcher, the wrist is snapped into semi-adduction and extension—*i. e.*, directly downward. The ball rolls off the upper or radial side of the index finger, and has imparted to it a rotation forward and downward.

In the production of the up-curve, or rising ball, so designated because it turns upward with the convexity of the curve downward, the arm is drawn

far back, the body is bent, and the arm then forcibly and quickly brought forward, with the hand near the knee. At this time the forearm is suddenly and forcibly supinated, and the wrist semi-adducted and extended, and the ball permitted to roll off the lowermost edge of the hand—*i. e.*, from the radial side of the index finger. This imparts to the ball a forward and upward rotation.

As has already been said, a combination of any of these curves is possible. For example, a ball delivered from the tips of the upturned fingers, with the rising-ball delivery, sends the ball upward, and causes it to descend before it reaches the batsman, and is known as the "snake ball," or rising drop.

The curving of the ball, or its lateral deviation from the proper line, is all due to the rotary motion imparted to it by the sudden, jerky, snapping motions of the forearm and hand, and pressure of the fingers. The curving is explained on the principle of the gyroscope. The peculiar and apparently awkward motion in pitching, is necessary to impart to the ball the proper gyration or twist, while the body movements are added to increase the speed of the ball in its passage from the pitcher to the batsman. Every pitcher has a somewhat different mode of delivery, and upon this depends the exact location of the disabling trouble under which he may be laboring.

PHYSIOLOGY.—The *in-curve* calls into action most particularly the pectoralis major, the biceps, brachialis anticus, and flexors of the forearm. The *out-curve* affects the pectoralis major, coraco-brachialis, infraspinatus, teres minor, and ulnar muscles. The *down-curve* strains most especially the pectoralis major, trapezuis, deltoid, and serratus magnus. The *up-curve* is mostly caused by the pectoralis major, biceps, and supinator brevis.

All kinds of pitching strain the elbow-joint. There is a tendency each time to a separation of the bones at the outer side of the joint—*i.e.*, radius and capitellum of the humerus. This is prevented, however, by the biceps, supinator longus, and extensor carpi radialis longior. The constant necessity for quick and forcible flexion of the elbow greatly strains the brachialis anticus; this is, therefore, one of the first among the muscles to feel the strain.

PATHOLOGY.—The changes induced by the exercise of pitching may affect muscles, ligaments, or bones. Secondarily, other structures may be involved, either by direct extension or by reflex action. Muscular changes manifest themselves in the usual stiffness or soreness the day after the exercise has been taken, or as much as two days later, without any special discomfort at the time of play or the day following. This muscular tenderness is due to hypernutrition caused by the excessive exercise. Adjustment follows in a few days, and everything assumes its normal course, for the circulation through the muscular tissue is then reduced to its usual requirement. On the other hand, daily exercise of the same character soon brings the muscle up to the requirement suggested by the increased supply of blood, and soreness soon disappears. What is true of muscles in this regard is also true of ligaments and bones. I feel quite certain that much of the soreness in either of these structures is due to accumulated excrementitious products, the result of sudden, transient, and excessive functional activity.

Muscles.—The brachialis anticus is probably most often the first to become painful and tender. The tenderness extends along the front and inner side of the lower third of the arm. The biceps participates in the tenderness soon after the preceding muscle, but it is usually only the lower half that is subject to pain. Examination of the arms of those in exercise or training will show that the lower end of the biceps belly becomes hard before the upper portion, and may be as firm almost as a piece of wood or bone, while the upper half is still capable of digital impression. The deltoid is also very commonly affected, and especially its posterior half, and more particularly in its upper portion. The pain may become so great that it is impossible to raise the elbow to the height of the shoulder, and the tenderness so marked that it is a decided relief to be divested of a coat, and a suspender is a positive load. The trapezius is often the seat of pain, but only, as a rule, along its upper or cervical border and a little below, just above those fibres which are attached to the scapular spine. The rhomboids and serratus magnus frequently become painful, the latter being strained in the delivery both of the out-curve and rising ball. The up-curve also greatly strains the latissimus dorsi; so, likewise, the drop-ball, for in both these deliveries the humerus is forcibly brought down toward the chest from an extended position. General soreness of the forearm muscles, both extensors and flexors, may be noticed, but this is mostly seen at the commencement of a season's work or in beginners. Sometimes there is moderate soreness of the triceps.

Ligaments.—The coraco-humeral is the one most affected in the shoulder-joint. Sometimes there is considerable pain in what has seemed to me, after careful study, to be the coraco-clavicular ligaments. Of all the shoulder ligaments, the acromio-clavicular are decidedly the most troublesome. This is readily understood when we take into consideration that in all the sudden and forcible movements incident to pitching, the acromio-clavicular joint is under an enormous and constantly recurring strain. The bones to which the ligaments of this articulation are attached are very porous, and thus apt to undergo changes from this strain. The external and internal lateral ligaments of the elbow are frequently the cause of lameness. They are subject to a great direct strain in all kinds of curve pitching. When congested or inflamed, they occasion the most excruciating pain, either at rest or during exercise. The wrist ligaments also become somewhat affected at times, but not to any very great extent. Occasionally much deep-seated pain is caused by a strained or congested condition of the radio-ulnar ligament

Bones.—That the bones are affected in the arms of pitchers, especially if the disability is of long standing, no longer admits of any doubt in my mind. The trouble is usually local and limited to the tendinous attachments of particular muscles and of ligaments and their immediate vicinity. Among these I would mention as most prominent the acro-

mio-clavicular joint, the outer border of the acromion process and outer end of the scapular spine, the tuberosities of the humerus, the middle of the outer side of the humerus, the two condyles, the bicipital tuberosity of the radius and the coronoid process of the ulna.

Symptoms.—Myalgia, ranging in degree from a simple soreness accompanied by stiffness to a high grade of tenderness, may be present along the anterior and inner aspects of the arm; it may exist in the fleshy cap of the shoulder; it is often found along the cervico-acromial arch, especially in its centre, and thence extends a few inches backward and downward across the fibres of the trapezius. Scapular and peri-scapular myalgia is frequent, especially in the rhomboid region.

Severer pain is felt in the involvement of the ligaments and tendons. These are readily discovered as thickened and tender by comparison with their fellows of the opposite arm. Pressure, even when light, causes marked pain, and tension causes intense suffering. This is readily produced, for instance in the elbow, by efforts at lateral motion at the joint, by which means the lateral ligaments are alternately put upon the stretch and relaxed. Fixation of the clavicle, while up and down, or to and fro motion is being made at the acromion, readily determines whether or not there is any affection of the acromio-clavicular ligaments. Passive motion of any of the joints having congested or inflamed ligaments or cartilage causes deep-seated and racking pain. The attempt to pitch with certain deliveries, for instance, as that which I have described for the rising ball, occasion a sudden, sharp, shooting, and intense pain to dart directly across and through the elbow-joint as would an electric shock. It passes from the inner to the outer side as a rule, though sometimes it is so rapid, practically instantaneous, that its direction cannot be determined. The pain, I believe, to be due to compression of tender structures, either ligamentous, cartilaginous, or osseous, or all, at the inner side of the joint, and tension of similar and surrounding parts upon the outer side.

The most severe, continuous, as well as sickening pains are due to the involvement of portions of the bones. I am well aware that I am treading upon new ground and subjecting the results of my investigation to sceptical criticism by the assertion that the bones are frequently involved in the affections of pitchers' arms. Nevertheless, I do say so most positively. The observation of a single case of long-enough standing and of sufficient severity will convince anyone that the trouble is largely osseous. It can be determined by comparison with the opposite limb, by the characteristic symptoms of osteitis and osseous congestions, and by the complete hardness of the bony enlargement.

These osteitic affections take place wherever the muscles that are most used have their attachments, and especially when the bone at the point of attachment is soft and porous. For this reason most trouble is encountered at the extremities of the bones. The rationale of bony involvement is simple when we consider the mode of insertion of muscles by their tendons to bone and also the attachment of the ligaments. The constant excessive pulling of the tendinous expansion upon the connective tissue framework of the bone calls for more work, more nutriment, more blood, and the result is hyperæmia, congestion, inflammation, proliferation, calcareous deposits—in short, a true osteitis resulting in a local hypertrophy of bone. Again, the periosteum is pulled upon and strained; its vessels, for a like reason as those of the bones, become gorged with more blood; periostitis eventually ensues, and with it more or less hypertrophy of the subjacent bone.

Treatment.—This may be prophylactic or curative.

Prophylaxis should consist in regular exercise or practice, regardless of the work done in a game. The practice should be of a remitting character. By this I mean that a pitcher, during practice, should work at his ease, and occasionally put on a spurt in speed and make an effort to do his best. Then he should lapse back again into easy work. These changes could be made a number of times during a single continuous practice of about one hour. Their frequency and duration must depend upon the condition of the pitcher at the time. When he has what is called an "off day," a day when he lacks natural interest in his work, it is well to do nothing but easy pitching. At no time should the exercise be violent, that is, straining, at the beginning. The reason for this is that in the complex and rapid movements of this exercise, together with the shallowness of the glenoid cavity, and the comparatively large size of the head of the humerus, it is easy either to dislocate the shoulder-joint or give it a bad wrench. Such an accident may disable one for a whole season if it does not do so permanently. Beginning the exercise with ease, and gradually increasing it, enables the muscles to accustom themselves to associate or coördinate work. The truth of this is borne out by the fact that most of the wrenches and dislocations that happen to ball players, occur in the early part of the season and in the early part of the game.

Pitchers, to be in "good form," should practise for about one hour every morning and afternoon, Sundays included. The exercise should be restricted to fifteen or twenty minutes for that half of any day in which regular work is to be done in a game.

All exercise should invariably take place in the sun, unless this is impossible because of cloudiness, or when work has to be done in-doors on account of rain. When the temperature in the shade falls below 60° F., it becomes risky to pitch with vigor. The risk increases in proportion as the temperature falls below this point. It is necessary, after severe out-door practice at a lower temperature than 60° F., to keep the body very warm, either by vigorous general exercise, such as walking; or, better still, by keeping in a warm room for one or two hours. This is all important at the beginning of the season with one who has been out of practice during the winter. An important fact to bear in mind, though seldom, if ever appreciated, is, that it is of vastly more importance to maintain a high temperature equably about the whole body, than taking good(?) care of the pitching arm and letting the rest of the

body take care of itself. This latter plan is the one usually followed, but is radically wrong.

Liniments should never be used on a pitcher's arm; or, in fact, on any part of the body of an athlete in case of pain from over-exertion. In the first place, they are utterly useless, as any number of impartial and disgusted sufferers can testify. Instead of mitigating the deep-seated pains, they add to them that of an irritant, especially if the liniment is "strong," and the result is a combination of superficial and deep pains. In the second place, if they contain aconite and if this constituent is absorbed, it benumbs the terminal nerve filaments and so lowers the maximum of muscular contractility as well as the rapidity of its responsiveness to the will and coördination reflexes. Morphia or opium and other anodynes are not unlikely to produce exactly similar results. That liniments sometimes have a good effect in these cases I do not deny, but the effect is mainly that of a much required placebo, and in such instances it is best to use a very mild, non-anodyne liniment, with plenty of hot flannel.

Rubbing, massage, and passive motion should invariably be discouraged. These manipulations are excellent substitutes for voluntary exercise in patients who are helpless or comparatively so, but they serve no beneficial purpose to a limb that has just ceased undergoing the severest kind of physical strain for one or two hours. Such a part requires temporary rest, and will do best without systematic exercise, though passive, till the next regular period for practice.

Regular exercise twice daily in the manner already indicated, should form the main treatment of a diseased pitching arm. Every other plan of treatment, to be permanently beneficial, must be subservient to this one idea. The object of continuous exercise is to encourage and bring to a climax and final completion those congestive and inflammatory processes in the muscles, ligaments, cartilage, and bones that lead to hypertrophy and necessary increase in strength. Some individuals are already so well endowed with these structures that additional growth is not required; others have small bones and weak muscles and ligaments with tender, or at least soft, articular cartilages. All such must be encouraged and nursed in their growth till it is completed. If this is intelligently managed, I predict that the owner of such an arm will never suffer damage in his arm from overwork, but may through accident or gross carelessness.

It is important to keep these nutritive or inflammatory changes within safe limits. When pain, tenderness, or swelling becomes excessive, it is well to make the exercise less violent and of shorter duration. Much of the pain experienced immediately after a game or practice may be abolished by position. As a rule, if the arm is held directly upward, preferably by another person without any effort on the part of the patient, there will speedily ensue a sense of comparative comfort. This I suppose to be due to the gravitation of some of the excess of blood contained in the arm back to the trunk, in this way relieving tension and pressure. A few gentle strokes from the hand along the arm down to the base of the shoulder facilitate the return of blood and hasten relief. Immersion of the whole upper extremity and shoulder into water at as high a temperature as can be tolerated, produces a most gratifying sensation of relief. This I suppose to be due to 1st, a general sedative effect and relaxation of the tissues; 2d, a dilatation of the superficial vessels causing an appreciable and beneficial depletion of those in the deeper and congested or inflamed structures; 3d, a quickening of the circulation, and consequently more rapid elimination of morbific material accumulated in the tissues during the excessive labor. If a rubber sleeve including the whole limb and fitting tightly about the base of the shoulder is applied with the arm held up over the head by an assistant, and the water turned into the sleeve, the result will be the combined effects of hot water and gravitation. This may be kept up for from five to thirty minutes, depending upon the severity of the pain, and upon the effects trials have shown it to have on that particular patient. The drying of the patient's arm must be done gently. There must be no vigorous rubbing or squeezing. He should not at all refrain from using it for ordinary purposes even if it be somewhat painful.

In severer cases, where there is an excess of inflammatory products, the best remedy is mild galvanism. The strength of current and length of time it is employed are determined by experience with the patient under treatment, and his own sensations. This seems to be the best rule. I have employed large flat electrodes, one in front and the other behind the elbow-joint. At the shoulder I would put one on top and the other at various painful points. As a rule, I apply both poles to sensitive parts. Occasionally it is well to break the current, though not often, and sometimes I reverse it. Mild galvanism is very gratifying and should be done in the evening, so that the nutritive changes induced by the passage of the current shall act undisturbed till the next morning.

It is of great importance that the kidneys, bowels, and skin should act very freely. It has been my experience that it makes little difference as to what or how much a pitcher eats so long as he follows a normal appetite, is without idiosyncrasies as regards diet, and leads a regular life free from excesses, provided the skin, kidneys and bowels act freely.

A languor often experienced after a game, and which prevents an appetite and interferes with digestion, is very often counteracted by a glass of cold milk. Beer has the same effect, but it is best never to order it, because it is often soon abused and the physician, as well as the patient, receives, and too often merits, blame.

In those cases where the pain is so severe that it becomes agonizing, and not only prevents sleep but elicits groans from the sufferer, it is necessary and beneficial to give a hypodermatic of morphia. It should be large enough to induce freedom from pain and permit sleep. The pain must have sunk to a minimum without the aid of an anodyne before pitching practice is resumed, and then it must be easy and very gradually increased. Sharp pains are always warnings that it is well to heed. Any kind of exertion

that will often cause a sharp pain has to be carefully studied; and a remedy will suggest itself that will result nine times out of ten in permitting the patient to pitch the same ball with either persevering and gradually increasing exercise of the same delivery, or some modification of it that experiment will show to be possible without pain.

My practical experience as an amateur ball player may help to convince that the points I have made are well founded. I developed a most excruciatingly painful right upper extremity from pitching. Every muscle, bone, and ligament, from the vertebral spines behind and the sternum and linea alba in front, to the right wrist, were in turn affected either singly or in groups. The pain and stiffness extended on the trunk between the right superior curved line of the occipital bone to the right iliac crest. Muscular soreness, fatigue, anorexia, fever, stiffness, and a loss of sleep from pain were for many weeks the rule. One night, after a hardly contested game, I was compelled to call up a friend from an adjoining room and have him administer mxv of Magendie's solution hypodermatically. The strongest liniments, both as regards counter-irritant and anodyne properties, were hopelessly ineffectual in making even the slightest beneficial impression.

My connection with a well-known athletic club and acquaintance with intelligent and college bred professional ball-players enabled me to see what could be done in the way I have already suggested for either prevention or cure. By adhering to my own plan of treatment, less the regular use of electricity, I was enabled to get entirely well and develop "staying qualities" at play that professional players have declared exceptional. This is mentioned simply to show what can be done by judicious management.

240 South Eighth Street.

PISTOL-SHOT WOUND OF ABDOMEN TREATED BY LAPAROTOMY AND SUTURING THE INTESTINES.[1]

BY R. A. KINLOCH, M.D.,
OF CHARLESTON, S. C.

JOSEPH B., colored, aged twenty-seven, was admitted into the City Hospital, January 21st, at 7.30 P.M. He had, two hours before, been shot in the abdomen with a pistol-ball (38-calibre), by a policeman, with whom he was struggling at the time. The ball had entered an inch and a half to the left of the umbilicus. There was also a slight wound of the scalp, supposed to have been received by falling after being shot. There was but little shock; patient seemed comfortable, with the exception of pain on the inside of the left thigh, which was intensified by movement of the limb. Pulse was 88, respiration 24, temperature 99°. He was given by the house-surgeon forty drops of tincture of opium, put to bed, abdomen carefully washed with a solution of bichloride of mercury (1 : 2000), iodoform sprinkled upon the wound, a compress of cotton placed over this, and retained by an abdominal bandage.

I visited the patient an hour after his admission into the hospital, and immediately directed the preparations for laparotomy. At 10 P.M., the preparations being complete, half a grain of morphia was given hypodermatically, and soon after anæsthesia was induced by the A.-C.-E. mixture. The little finger was first passed into the wound, and subsequently a Nélaton porcelain-ball probe, to verify the fact of the entrance of the projectile into the peritoneal cavity. The cavity was then opened into by an incision eight inches in length, upon the median line, extending from the umbilicus to just above the pubes. The incision was made under a weak carbolic spray. The intestines were carefully drawn out and examined piece by piece. Soft, clean towels, wrung out of a warm solution of bichloride of mercury (1 : 10,000), were used for covering the intestines as the examination proceeded. The jejunum was found to have four perforations—two were orifices of entrance and two of exit. The ileum had two perforations—one of entrance and one of exit. The mesentery was perforated in two places, and was besides badly torn. One of the vessels of the mesentery was bleeding freely. The hemorrhage was at once controlled by pressure-forceps, and subsequently by a fine silk antiseptic ligature. There was a considerable amount of blood, fluid and clotted, in the cavity. All the wounds were closed, without paring, by means of a delicate, round, smooth, straight needle carrying fine antiseptic silk, forming the Lembert suture. The large wound in the mesentery was as carefully brought together as possible, but it was noticed that at this point there was an extensive infiltration of blood which could not be removed. The cavity was carefully cleansed, and washed out with the weak solution of bichloride of mercury.

Much difficulty was experienced in returning the intestines into the cavity, because of the rigidity of the abdominal parietes. The abdominal wound was closed by deep silver wire sutures, and superficial sutures of fine antiseptic silk. A large rubber drainage tube was inserted, and the wound dressed with iodoform, cotton, and a sublimate bandage. During the operation, which was necessarily protracted, three hypodermatic injections of sulphuric ether and tincture of digitalis were administered. The patient was in very good condition when removed from the operating-table to his bed. Now another hypodermatic of half a grain of morphia was given. Cracked ice in small quantities was allowed.

January 22, 6.30 A.M. Pulse 108, respiration 36, temperature 101°. Allowed a spoonful of milk and lime water occasionally, if not nauseated. Morphia, if required to relieve pain and insure quiet. Incontinence of urine was noticed. At 5 P.M., pulse 118, respiration 25, temperature 100°.

23d. At 12 midnight, pulse 108, respiration 32, temperature 100°. 3 A.M., pulse 118, respiration 32, temperature 102.9°. 6 A.M., pulse 104, respiration 28, temperature 101.4°. At 8.30 A.M. vomiting occurred. I visited the patient soon after this,

[1] Read before the American Surgical Association, May 12 1887.

and upon examining the drainage tube and wound, found that one of the wire sutures had broken, and a small knuckle of intestine was protruding through the middle of the wound. There had been some bloody serum discharged through the tube. I disinfected the wound, carefully returned the intestine, and closed the gap in the wound by a stout antiseptic silk suture. The patient made no special complaint of pain. Drainage tube was removed. Small quantities of peptonized milk allowed, if the stomach should be quiet. Morphia, if necessary.

At 2.30 P.M. Pulse 120, resp. 20, temp. 102°.

At 5 P.M. Pulse 108, resp. 25, temp. 102°.

At 9 P.M. slight vomiting again occurred. Nothing but ice had been taken. Vomiting occurred at intervals during the next two hours, then ceased for one hour, and again recurred. At 12.15 A.M. the patient suddenly died.

Post mortem (sixteen hours after death). Abdomen alone examined. This was greatly distended. Two more of the wire sutures had parted, as the consequence of the post-mortem gaseous distention of abdomen. No adhesion of the parietal peritoneum at wound; about half a pint of dark serosanguinolent fluid in cavity; patches of lymphy exudation upon serous surface of intestines and parietal peritoneum; intestines generally hyperæmic; all of the intestinal wounds that had been sutured were closed, and at some points the convolutions of the gut were slightly adherent to the parietal peritoneum; all of the sutures were buried by the exudation, showing that good repair had begun; no fecal extravasation; a portion of the rent in the mesentery was gaping; a circumscribed abscess was discovered in the meso-colon, to the right of the vertebral column, and out of the line of direction of the bullet—this, said my medical friend who conducted the autopsy, "looked like the breaking down of a caseous lymphatic gland." The bullet was found in the soft parts behind the body of the fourth lumbar vertebra, on the left side, it having in its passage cut away a portion of the body of the vertebra; kidneys congested and ecchymotic.

Remarks.—The present attitude of laparotomy for traumatism is such that it should be regarded as imperative with the profession to report every case occurring in practice. The very limited number of cases of operation for bullet wounds of the abdomen, without protrusion of the viscera, that have been reported, are not sufficient to furnish valuable statistical evidence. Nor is the contrast between the results obtained by the active and the passive treatment in such cases yet sufficient to elicit a unanimous verdict from experienced clinicians.

The case whose clinical history I have just read, is the third in which I have practised free abdominal section for bullet wounds of the abdomen without visceral protrusion. The time between my first and third operation is about twenty-three years. This long interval between these operations is explicable simply from the fact that cases where such practice could be instituted have rarely occurred to me. Upon two occasions, since my first operation, I have seen patients recover without interference. In one of these, the lapse of time before the case was seen rendered interference unadvisable; in the other, operation was rejected by the sufferer and his friends.

The limited number of laparotomies for wounds of this kind, done in the civilized world during the past twenty-three years, my operation of 1863 being regarded as the first, would lead to the inference that the procedure has not during this time been accepted by a large number of the surgeons of the world. This may be regarded either as an evidence of conservatism, or as a rejection of bold and venturesome effort because of its apparent inhumanity.

Upon the publication, in 1882, of my second case, a fatal one, I used these words: "While this adds another fatal case to the short list of those in which similar treatment has been instituted, it does not alter my belief in the correctness of the practice in the class of injuries presenting so gloomy a prognosis."

Again, I said: "While not as hopeful as my distinguished friend Dr. Sims, because of the success of ovariotomy, I do look forward to better results than have been so far obtained." "Listerism, and much of the knowledge acquired by the ovariotomists," I suggested, "would soon embolden surgeons, who had heretofore favored the passive policy, and give us fuller statistics upon which to reach conclusions." This opinion has begun to be verified, but the progress, if I can call it such, has been slower than a sanguine surgeon could have expected. Dr. Thomas S. K. Morton, in a valuable paper (The Medical News, Feb. 19, 1887) entitled "Abdominal Section for Traumatism," read before the Philadelphia County Medical Society, on January 26, 1887 (and which paper anticipated much that I had purposed saying upon this occasion), gives, as he says, the result afforded by canvassing the literature of the world, and furnishing an abstract of every case which he had been able to find. The total number of cases of abdominal section for traumatism, as given, is only 57. But 22 of these were cases of gunshot wounds. Of the 57 cases, 36 died, and 21 recovered, a mortality of 63 per cent. Of the 22 gunshot cases, 5 recovered and 17 died, a mortality of 77 per cent.

The gunshot cases alone concern us at present, but I trust I may be excused for alluding to one matter which personally interests me.

"The first case of abdominal section for traumatism," says Dr. Morton, "was that of Dr. Walters, of Pittsburg, for ruptured bladder, in 1862. The first successful case was the same. The first after Walters was that of Heath, in 1876. The first recovery after Walters case was that of Dr. W. O. Roberts, done for stab-wound, August 28, 1882.

"By the term abdominal section for traumatism, is meant to include those cases where the operator deliberately opens the belly or greatly enlarges an existant wound for the purpose of discovering intraperitoneal wounds, and, if they are present, repairing them as far as possible, together with more or less final cleansing of the peritoneal cavity."

My first operation was performed May 27, 1863. This was for traumatism most certainly; and, to say nothing of its being for gunshot injury, it should stand next to Walters's case, and before Heath's of

1876. My case recovered; so, in this regard too, the case precedes Roberts's of 1882. It most assuredly comes within Dr. Morton's definition of traumatism.

In this operation for gunshot wound, I deliberately opened the belly, repaired intraperitoneal wounds, and cleansed the peritoneal cavity. Again, Dr. Morton alludes to my case of 1881 as "the first recorded case of gunshot wound treated by abdominal section." "The first recovery of gunshot case," he says, "was the case of Kocher, of Switzerland, in 1883." And afterward he says: "The first recovery was a case operated on by Dr. William T. Bull, of New York, in 1884." Dr. Morton intended, no doubt, to say that Dr. Bull's case was the first recovery in this country. In this he is correct. If my first operation of 1863 is to be excluded from the category of laparotomies for gunshot wound of the abdomen, and my case of 1881 recognized as the first case on record. This question I will leave for others to decide, it concerns me only so far as it pertains to the history of the operation. It is true that the operation of 1863 was practised seven months after reception of the wound. Nutrition of my patient was failing rapidly; there had been but one discharge per rectum, and that only the contents of the lower bowel, since the reception of the wound, and inevitable death was in the near future. Now it was that *laparotomy for gunshot wound, without protrusion of viscera, was done for the first time.*

In my publication of the case I urged this practice as applicable to recent gunshot wounds of the abdomen without protrusion. I put forward the success obtained as an argument against the almost universal practice of abandoning intestinal lesions of this kind to nature, rather than to risk opening boldly the peritoneal cavity. I expressed the opinion that the result of the operation should serve to encourage that hopefulness and boldness so essential to progressive surgery, and at all times preferable to despair.

Since the publication of Dr. Morton's statistics there have been several additional reports of operations to be added to the list. The cases of Dr. Packard, of Philadelphia, and Dr. C. Kollock, of Cheraw, S. C., now occur to me. The latter was a successful operation, and one worthy of notice, because of the confidence exhibited by the surgeon in his art, and the recovery of the patient under most adverse surroundings. The operation was done in a negro cabin, without professional assistance, and without the opportunity of carrying out antiseptic precautions.

The signs of our times, I now may be permitted to say, are most hopeful. Surgeons are beginning to accept the argument of Baudens, long ago so boldly and happily expressed. No longer, I trust, will the fear of being regarded inhuman, or too bold, "stay the hand that alone can preserve the days of a dying man." Humanity is not to be illustrated by inactivity or stoical indifference. The rule of conduct, as said Baudens, should rather be the well-known aphorism, "*nullus anceps medium aquam nullam.*"

There are several points of special interest connected with the clinical history of this case, to which I will briefly advert. First. The absence of symptoms thought to be of diagnostic value in intestinal lesions from bullet wounds. There was no marked shock, no escape of fecal matter from the abdominal wound, no sudden meteorism. To have relied upon this negative evidence, and to have resorted to a passive treatment under the assumption that there was no intestinal lesion, would, it is true, have been of no detriment to this patient, as the result proved, yet I would have been led far away from a correct diagnosis.

Second. From the numerous intestinal perforations there was no escape of fecal matter into the peritoneal cavity. I have upon another occasion called attention to this fact as one not to be passed over in connection with our reasoning as to the propriety of an active or a passive treatment in gunshot wounds of the abdomen. (*Journal of Amer. Med. Association*, Dec. 18, 1886.) It is certainly an argument to be used against the active treatment. The prevailing idea is that general peritonitis arises from fecal extravasations, and that the indication for laparotomy is mainly founded upon the necessity of obviating or removing this supposed cause. To quote merely from two high American authorities: says Gross, in his *System of Surgery*, "the great danger is from fecal effusion, and such effusion is almost inevitable, even when the opening of the intestine is of a very small extent." Says Hamilton, in his *Treatise on Military Surgery and Hygiene*, "It is equally true that death, in a great majority of cases, is caused by extravasation of the contents of the bowels into the peritoneal cavity, and the consequent inflammation."

It is, indeed, difficult to explain the absence of fecal extravasation in the more fearful intestinal lesions, however easy it may be to understand this in cases of very slight wounds. I desire only to offer my clinical experience in corroboration of what has been observed by others. The spasmodic rigidity and hardness of portions of intestines injured have been noted by Baudens, and suggested as a diagnostic sign to be recollected when the finger is to be passed through the parietal wound into the peritoneal cavity. I particularly observed, in my investigation, that the intestinal perforations were measurably closed by the crowding of the mucous and muscular coats of the bowel into the wounds of the peritoneal layer, these tissues seeming to act like a cork in preventing the escape of the fluid contents. Paralysis of the tube, the result of the severe shock and injury, may, by preventing peri-taltic action, explain to some extent the absence of fecal exudation. Gross, in his *Experimental and Critical Inquiry into the Nature and Treatment of the Wounds of the Intestines*, tells us of the marked contraction and eversion of incised wounds of the intestines, by which the extent of the wound becomes much reduced. The experiments of Mr. Travers to prove that fecal extravasation was not a necessary consequence of punctured and incised wounds of the intestines are familiar to all. Mr. Erichsen, among the most prominent of modern surgeons, has affirmed that "it is seldom that feces are extravasated from a gut that is not protruding, unless it be very full at the time of injury, or the wound in it be very large."

He cites two cases of shot wounds of the intestine, coming within his own observation, to bear him out in this assertion. There are also others who have entertained similar views. In the *Surgical History of the War of the Rebellion*, Dr. Otis notices these recorded observations, and, in his enthusiasm for *his* side of the argument, pronounces them "dangerous fallacies." The truth most probably is, that the cases in which there is no fecal extravasation constitute exceptions to the general rule. In any investigations of scientific truth it is well for one to present fairly the arguments which seem to militate against his own view of the case, and it is with this idea that I have called attention to the above facts.

Third. I have in both of my fatal cases, been impressed with the little suffering experienced by the wounded, and their almost painless death. This is contrary to general observation and belief in cases of acute general peritonitis. As a rule, death comes quickly. With "hyper acute peritonitis," says Baudens, "life is prolonged scarcely more than twenty-four hours." But, in the language of John Bell, death is not easy: "there soon come on dreadful pain and vomiting, costiveness, hiccough, the torments of the *miserere mei*, and the patient in great anguish expires." Where gangrene results there may be a "deceitful ease," a slower and less painful death. How is this absence of suffering to be explained? It is probable that the use of the drainage tube, admitting of the escape of the inflammatory effusion, and thus relieving belly tension, may have something to do with it.

The treatment of acute peritonitis by abdominal section has been proposed and practised. Should relief from pain follow upon such practice, it may be explicable upon the same principle. This may be advanced as another argument for laparotomy in intestinal wounds, for next to the cure of disease we look to the satisfaction coming of a painless death—the humanity of a bold practice.

Fourth. The fatal termination of a case like the one I have reported should not be used as an argument against the treatment by laparotomy. Abdominal wounds, the precise nature and extent of which can scarcely be revealed before operation, must often prove as fatal as are cases of brain and heart injuries which are at once fully recognized. Prognosis must at times not be announced until suggested by diagnosis. This case is one in point. The injury to the mesentery, apart from the numerous intestinal perforations, was, perhaps, sufficient to insure a fatal result, by its consequent peritonitis and sepsis. The surroundings of the case were unfavorable to operation, as all will admit who know anything of a negro hospital in a southern latitude. The rupture of one of the wire sutures, and the consequent hernial protrusion, was most unfortunate. I cannot pretend to say how far this may have influenced the destructive processes which eventuated in death. At the time of operation I objected to the character of the wire handed me for use, fearing that it had not the necessary strength. It happened to be all that was in the hospital at the time, and had to be accepted. The tension of the abdominal walls in the powerfully muscular subject delayed the operative procedure, and was a formidable obstacle to the return of the intestines into the cavity, and the keeping of them there. To some extent this tension was increased, as inflammatory results appeared, and thus the strain upon the sutures was more than they could bear.

The formation of a circumscribed abscess in the meso-colon in so short a period of time, I allude to, in conclusion, as a striking feature in the pathology of the case.

CASES OF CHEESE POISONING.

BY SHIPPEN WALLACE,
CHEMIST TO THE NEW JERSEY STATE BOARD OF HEALTH AND TO THE STATE DAIRY COMMISSIONER.

On January 20th last, over fifty persons were suddenly taken ill at Jeanesville, Pa. The symptoms were the same in all the cases, and on investigation by the physician, he was led to the belief that the cause arose from cheese which had been purchased at the village store.

Portions of the suspected cheese, obtained from the families of those who were ill, were sent to me for analysis. I was, from the symptoms, led to suspect tyrotoxicon as the cause, which proved to be correct on analysis, the chemical reactions not only being obtained, but also the physiological test: a cat having been made quite sick after partaking of milk to which a small quantity of the isolated tyrotoxicon had been added.

During the past month a similar outbreak of sickness, but not affecting so many persons, took place at Riverton, N. J., and on the analysis of the cheese which the attending physician suspected to be the cause, I also found tyrotoxicon to be present. In both instances no deaths occurred, the patients recovering with proper treatment.

There can be no doubt that the cheese was the cause in both instances. In the Riverton case, in one family of seven, all partook of the same food with the exception of one, who ate the same that the others did, but did not partake of the cheese. All but this one were taken sick within a few hours; and while in the Jeanesville case there were a few who were not made ill, yet all who were had eaten of the cheese to a greater or less extent. Dr. E. B. Doolittle, of Jeanesville, had charge of the cases there, and gives the following account of the symptoms: "There were at least fifty persons poisoned by this cheese. There were also eight others who ate of the cheese, but felt no unpleasant effects; whether this was due to personal idiosyncrasy or to an uneven distribution of the poison throughout the cheese, I am unable to say.

"The majority, however, comprising fifty or sixty persons, were seized in from two to four hours after eating the cheese with vertigo, nausea, vomiting, and severe rigors, though varying in their order of appearance and in severity in different cases. The vomiting and chills were the most constant and severe symptoms in all the cases, and were soon followed by severe pain in the epigastric region, cramps in the feet and lower limbs, purging and griping pain in the bowels, a sensation of numbness or pins and needles, especially in the limbs, and, lastly, very

marked prostration, amounting almost to collapse, in a few cases.

"The vomit at first consisted of the contents of the stomach, and had a strong odor of cheese, afterward it consisted of mucus, bile, and in three or four of the severest cases blood was mixed with the mucus in small quantities. Microscopic examination of the same was not made, but to the eye it appeared as such. The vomiting and diarrhœa lasted from two to twelve hours. The rigors and muscular cramps, one to two hours. The diarrhœa, at first fecal, became later watery and light-colored. No deaths occurred, and for the most part the effects were transient, and all that remained on the following day were the prostration and numbness; the latter occurred in about one-half of the cases, and disappeared in from one to three days.

"Children, as a rule, seemed to suffer less than adults, and, of course, it was not possible to elicit as definite symptoms from them. The suddenness of the attack was remarked by all; some feeling perfectly well until the moment of attack. Nor did the symptoms seem to be in proportion to the amount of cheese taken. Some of the severest cases declared they had not eaten more than a cubic inch of it. One of the severest cases was about six and a half months pregnant, but no interference with pregnancy occurred. All the cheese which caused the sickness came from the same piece."

This outbreak is the largest of the kind of which we have a record since the one in Michigan a few years since, which resulted in Prof. Vaughan discovering the cause, and giving the toxic substance its name, tyrotoxicon—cheese poison.

Last summer, at Long Branch, forty-three persons were taken ill, caused by this same agent in milk (THE MEDICAL NEWS, September 25, 1886), and lately at Memphis there was a similar outbreak.

To Dr. Vaughan is due the credit of the discovery of tyrotoxicon, and while we find in the *Lancet* of January 29, 1887, an article on a poisonous ptomaine in milk, to which the writer proposes the name "lactotoxine," and expresses his ignorance of any literature bearing on the subject, yet on reading the article one is struck with the great similarity and arrangement of symptoms, and method of analysis there found, to the article written by Dr. Vaughan, and if the writer was as ignorant as he states, it certainly affords a very striking coincident.

Of what tyrotoxicon is, *chemically*, we are at present ignorant, but there can be little doubt that we shall soon know, as Dr. Vaughan is engaged in its study, and has already published an extremely interesting "preliminary note" (THE MEDICAL NEWS, April 2, 1887).

Its cause and origin are, undoubtedly, to be found in a fermentation of the milk, caused by improper treatment after milking (THE MEDICAL NEWS, September 25, 1885), and that it is already in the milk from which the cheese is made, and is not formed in the cheese, but only perhaps increased in quantity, is not only possible but probable. If such is the case, greater attention on the part of manufacturers to the care of the milk, would result in obviating its presence.

In opposition to the above theory, however, is the fact that all "cheeses of a batch" do not contain it, but unfortunately we cannot trace back the history of a cheese to the time when it was milk, with the certainty that we can and have traced milk which has caused illness. In the Jeanesville case the cheese causing the illness was one of a lot of thirty which were received at the same time from the factory; twenty-seven had been sold, and no illness resulted; but it was, of course, impossible to learn the history of the cheeses back to the time when the cows were milked.

HOSPITAL NOTES.

TREATMENT OF CHOLERA INFANTUM IN THE PHILADELPHIA HOSPITALS.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

DR. LOUIS STARR, in the treatment of entero-colitis in the clinic for children, gives great prominence to the hygienic management. The following points are insisted upon:

a. Fresh air must be secured by taking the child to a public square in the cool of the morning and evening, or, better still, by a morning or evening trip on one of the river steamboats. The heat of the day must be spent in as cool a room as can be had. Coddling is discouraged, as many a stout mother has hastened her infant's death by too fond and constant nursing in the arms.

b. The clothing must be as thin as possible, provided, always, that woollen be worn next the skin.

c. Twice, or three times a day in very hot weather, the whole surface of the body must be sponged with water at a temperature of 80° F., and dried with gentle rubbing. The addition of rock salt renders these baths more bracing. Full warm baths must supplant the cold spongings if there be much prostration.

d. Diet most carefully regulated as to quality, quantity, and intervals of administration. Sound cow's milk must form the basis of the food in bottle-fed babies. Fairchild's peptogenic powder is very useful in artificial feeding.

Medicinal treatment varies with the case. Should the patient be seen early in the attack, it is initiated by a laxative. A teaspoonful of castor oil with five drops of paregoric, or the same quantity of spiced syrup of rhubarb, is sufficient for an infant of one year. Afterward, while the stools are yellow, homogeneous, and not very frequent, alkalies and astringents are employed, as:

℞.—Sodii bicarb. . . . . gr. xxxvj.
Syrupi rhei aromat. . . . f℥ss.
Misturæ cretæ . q. s. ad f℥iij.—M.

S.—One teaspoonful every two hours, for a child of one year.[1]

When the stools are frequent, green, and acid in reaction, small doses of opium are added to the alkali; for example:

℞.—Tr. opii deod. . . . . ♏vj.
Bismuthi subcarb. . . . gr. lxxij.
Syrupi . . . . . f℥ss.
Misturæ cretæ . q. s. ad f℥iij.—M.

S.—One teaspoonful every two hours.

[1] All prescriptions given are calculated for this age.

At the same time, the skin of the whole abdomen is reddened, two or three times a day, with a weak mustard draught—one part of mustard to five of flour.

If the evacuations be liquid and contain whitish or greenish flakes, and the above treatment fail after a fair trial, good results often follow a short mercurial course; thus:

℞.—Pulv. ipecac. comp. . . gr. ij.
Hydrarg. chlorid. mit. . . gr. ½.
Cretæ præparat. . . . gr. xxxvj.
M. et ft. chart No. xij.

S.—One powder every two hours for twenty-four or forty-eight hours, or until the stools become yellow and homogeneous.

Should the stools be frequent and serous, more powerful astringents are used, as aromatic sulphuric acid, nitrate of silver, or oxide of zinc.

When the stomach is very irritable, rectal injections are resorted to, the drugs used being tincture of opium, nitrate of silver, and ipecacuanha. Ipecacuanha is chosen when there is much tenesmus with the discharge of blood and mucus. It may be administered as follows:

℞.—Ext. ipecac. fld. . . . ♏xij.
Tr. opii deod. . . . ♏viij.
Mucilag. acaciæ . q. s. ad f℥ij.—M.

S.—Inject one tablespoonful every four hours.

Stimulants—wine of pepsin, brandy, or whiskey—are given when there is prostration.

In cases of recovery, the diet and hygiene are carefully watched until all danger of a relapse has passed; the astringents, etc., are gradually dropped, and digestants and tonics ordered.

The antiseptic treatment recommended by L. Emmett Holt has lately been tried with good results. It embraces the careful attention to regimen already alluded to, preliminary evacuation of the bowels with castor oil, and the administration of naphthalin. The latter is usually ordered as follows:

℞.—Naphthalin,
Ground coffee . . . . ää gr. vj.
Sugar of milk . . . . gr. xxiv.

M. et ft. chart No. xij.

S.—One powder every two hours.

In the whole conduct of our cases, the greatest care is taken to avoid locking the bowels.

Philadelphia Hospital.

Dr. John M. Keating holds that the question of summer complaints may be considered under three heads, viz., simple indigestion, the inflammatory form, and the septic. These may be distinct, or they may be combined in the same case.

Too little stress has been laid upon the inherited feebleness of the digestive organs in many children. One is often surprised at the failure which meets the attempt to bring up a child on the bottle, notwithstanding every precaution be used. In these cases the digestive function is at fault—the infants are dyspeptic. Every child is a study in itself. Family idiosyncrasies have to be taken into consideration. "Bringing up by hand" is a science, and cannot be left to the nurse, however faithful and accomplished she may be.

At this time of the year, the simpler forms of diarrhœa are due to indigestion. The child is enfeebled by the intense heat, the teething process irritates its nervous system or affects its mucous membranes; the stools become frequent and watery, become greenish or at times are colorless, and then there are flatulence and pain. If the baby be in the city, these symptoms may come on suddenly and with great intensity; there may be, also, vomiting and fever, with evidence of cerebral excitation. The treatment of such a case should be as follows: Absolute rest; the child should be kept in as cool a place as possible. *Its bottle should be stopped at once*, and for a few hours its diet should be limited to cool gum-arabic water, with lime-water, wine whey, if there is much prostration, or a small amount at a time of Valentine's beef juice, with wine of pepsine. Toast water, or egg-albumen water, may be used to vary the diet if the attack persists for several days. Counter-irritation by hot foot-baths, flannels saturated with essence of ginger, or spice poultices to the abdomen, are very useful; and the gums should always be examined, and lanced if necessary, or the child should be given a soft handkerchief, soaked in ice-water, to suck or bite on. As for the medicinal treatment, we should use those preparations that allay gastric irritability.

℞.—Hydrarg. chl. mitis . . . gr. 1/12.
Ext. pancreatis (Fairchild) . gr. j.
Sodæ bicarb. . . . . gr. j.—M.

One every hour.

This Dr. Keating has found to be of great service; or,

℞.—Bismuthi subnit. . . . gr. j.
Pepsini sacch. . . . . gr. ij.
Pulv. aromat. . . . . gr. j.—M.

But, and this is very important, if there be vomiting, and the passages contain curds, he would prefer to give

℞.—Hydrarg. chl. mitis . . . gr. 1/12.
Pulv. ipecac. . . . . gr. 1/4.
Sodæ bicarb. . . . . gr. j.—M.

One every half hour till six are given, and then the following every hour until the stools are free from curds and normal in color:

℞.—Ol. ricini . . . . . gtt. x.
Pulv. acac. . . . . gr. ij.
Syr. rhei aromat. . . . gtt. v.
Spts. vini gal. . . . . gtt. x.
Aquæ menth. pip. . q. s. ad f℥ij.—M.

Should there be much flatulence, mucus in the stools, straining, vomiting, and fever—in other words, the symptoms of entero-colitis—the castor-oil prescription is the one to be preferred, and he advises the salicylate of soda in half-grain doses to be incorporated with it.

When the stomach is very irritable, all feeding should be avoided by the mouth; and in such cases an enema of gum-arabic water with the yelk of an egg, about two ounces every three hours, immediately after a stool, may be given till the stomach is tolerant. When the bottle is resumed he advises boiled milk prepared with arrowroot or rice in small amounts.

He uses white whey freely in cases where there is much prostration, made less laxative by mixing with toast water or gum-arabic water. The mucous membranes certainly are affected by the heat as well as the serous membranes, and on that account the temperature of these cases should be watched and controlled by refrigerant measures, or even quinine or antifebrin. Undoubtedly a large proportion of cases of summer diarrhœa are due to some septic influence, especially when they assume the choleraic form. The suddenness of onset, the evidence of vasomotor paralysis, the exhaustive discharge, call for immediate treatment of the most energetic character. The mild, unirritating diet which has just been outlined should be rigidly enforced; without it, medicinal treatment is of little avail. The child should be frequently sponged to keep the temperature down and the skin active. Sweet spirits of nitre should be used to keep the kidneys active and as a sedative; and if the pain seems severe and the movements are watery and frequent, the following may be given at intervals of one hour:

℞.—Hydrarg. chl. mitis . . . . gr. $\frac{1}{12}$.
Pulv. Doveri . . . . gr. $\frac{1}{2}$.
Sodæ bicarb. . . . . gr. j.—M.
Ft. chart. j.

Should there be vomiting and a profuse serous diarrhœa with pain, the following will probably answer better:

℞.—Morphiæ sulph. . . . . gr. $\frac{1}{4}$.
Acid. sulphuric. aromat. . . . gtt. xxxij.
Spts. vini gallici . . . . ʒj.
Syr. acac. . . . . fʒss.
Aq. menth. pip. . q. s. ad fʒij.—M.
Dessertspoonful every two hours for a child a year old.

Or, if there is any reason to contraindicate the use of morphia, use the following:

℞.—Sodæ salicylat. . . . . gr. viij.
Spts. chloroformi . . . . gtt. xxxij.
Syr. zingib. . . . . ʒj.
Syr. acac. . . . . ʒij.
Aq. menth. pip. . q. s. ad fʒj.—M.
Teaspoonful every hour. Shake well.

If in these cases the vomiting still persists, the following has served a good purpose:

℞.—Sodæ salicylat. . . . . gr. j.
Bismuth. subnit. . . . . gr. j.
Pulv. acaciæ . . . . . gr. ij.

Repeated every hour; and sustain the child by very small quantities of wine whey—not more than a teaspoonful at a time.

When excellent and powerful astringents and opiates are required, use the following:

℞.—Tinct. kino comp.[1] . . . . gtt. xl.
Syr. rhei aromat. . . . . fʒj.
Spts. vini gallici . . . . fʒj.
Syr. acaciæ . . q. s. ad fʒj.

Sig.—Teaspoonful in water after every movement; and this formula can be varied by adding bismuth salicylate, or chalk if necessary, or dilute or aromatic sulphuric acid.

In all cases of cholera infantum the antiseptic treatment is the most valuable, using creasote, carbolic acid, resorcin, calomel, corrosive sublimate, p. r. n.

Dr. Keating was one of the first to advocate the use of the salicylate of soda in this form of diarrhœa, using salicylic acid in half grain doses with the preparation known as soda mint. Its advantages are that it is cholagogue as well as antiseptic.

EPISCOPAL HOSPITAL.

DR. F. P. HENRY, in the treatment of summer diarrhœa, believes intestinal antisepsis to be an important indication. Convulsions, or other symptoms of profound intoxication, occurring at the outset of such an attack, may be reasonably attributed, in the absence of direct chemical proof, to the presence of tyrotoxicon or other poisonous ptomaines, in the ingested food. The same symptoms occurring at a later stage, are more probably due to the formation of such substances in the intestine, for it is established that they are produced in abnormal quantity in catarrhs of the gastro-intestinal tract. Whether introduced from without or formed within, an attempt should be made to prevent their disastrous effects upon the system. With this object in view, he has recently prescribed, with excellent results, the sodium salicylate, as recommended by Dr. Emmett Holt, of New York. He gives it with bismuth, as in the following formula:

℞.—Bismuth. subnitrat. . . . ʒj.
Sodii salicylat. . . . . ʒss.
Syr. acaciæ . . . . ʒj.
Aquæ . . . q. s. ad ʒij.—M.

For a child of from one to three years of age, a teaspoonful may be given every two or three hours. For older children, able to swallow a pill, thymol, which is undoubtedly one of the best known intestinal antiseptics, may be administered. It may be given in doses of one grain three or more times daily. It is very insoluble, and is best made into a pill with medicinal soap.

With reference to the still more important question of diet, it is sometimes necessary for a child to abstain for a time from its customary supply of milk, and live on mutton broth, clam juice, and barley water. In certain cases, milk appears to undergo changes which render it irritating to the bowels, and poisonous to the system. A substitute for milk may be found in some one of the numerous foods for infants, of which the soluble food of Carnrick is one of the best.

MEDICAL PROGRESS.

NAPHTHALOL.—KOBERT, of Dorpat, writes as follows regarding the use and constitution of this substance, in the *Therapeutische Monatshefte* for May, 1887:

Salol was introduced by Nencki, of Berlin, who sought to substitute a less irritating compound for sodium salicylate. It was made by putting in the place of the salicylic radicle phenol or carbolic acid, to the extent of 38 per cent. When given in amounts of ʒi ½ or ʒ2 daily, unpleasant cerebral symptoms have followed, referable to the carbolic element in the compound.

[1] This preparation, well known in Philadelphia, contains gum, camphor and opium.

Naphthalol is formed by substituting for the carbolic element, a less irritating substance known as beta-naphthol. Kobert has experimented with the following results, using this compound:

1. This substance is insoluble in water, odorless, tasteless, and is not dissolved or decomposed by the acid contents of the stomach, or by pepsine.

2. In contrast to the above, this substance is readily decomposed by the pancreatic ferments, and by the ferments produced by the mucous membrane of the living intestine. Salol, made with carbolic acid, is decomposed by pancreatic ferment only.

3. The mucous membrane of the large intestine in its upper portion, possesses the same power of decomposition as that of the small intestine; this property is diminished in the lower portion of the bowels.

4. Gastric disturbances and cerebral confusion were not produced by doses of four and a half to eight grains four times daily.

5. This substance appears in the urine in the same form in which salicylic acid appears—as a body turning ferric chloride a violet color.

6. Its continued use was well borne; animals bear forty or fifty grains for two days without injury.

7. In vesical catarrh, with alkaline and foul urine, its effects are most happy; the urine becoming clear and acid, and pain decreasing.

8. It is useful in acute joint rheumatism, and indicated in intestinal decompositions.

9. When added to culture materials it is not so powerful an antiseptic as phenol salol.

Palliative Incision in Tuberculous Peritonitis.—Breisky has operated upon a case as follows:

The patient was a woman, in whose case a diagnosis of ovarian tumor had been made. On examination pulmonary tuberculosis was found; no tumor of the abdomen or affection of the uterus and appendages was present; the abdomen was filled with fluid. Aspiration gave twelve quarts of clear serous fluid, whose examination was negative. High fever continued, and the fluid accumulated again in eight days.

On incising the abdomen an extensive tuberculosis of the intestines was discovered, the genital organs being free. A small piece of peritoneum was excised for examination, and the wound dressed with iodoform gauze. Abdominal trouble ceased entirely after the operation; healing by first intention followed. The pulmonary tuberculosis was not influenced by the operation.—*Centralblatt für gesammte Therapie*, June, 1887.

Terpine and Terpinol.—Chéron gives the following formulæ for terpine—hydrated turpentine—and terpinol—an oily, volatile derivative of terpine, made by boiling terpine with pure water, or water acidulated with hydrochloric or sulphuric acid.

Terpine	gr. 75.
Glycerine	
Alcohol (95 per cent.)	āā ℥ 2½.
Simple syrup	

Terpine may be given to the extent of eight grains daily for chronic bronchitis, and in the same quantity for neuralgia.

Terpinol may be given in capsules or pills.

Terpinol,	
Benzoate of soda	āā gr. 1½.
Sugar	q. s.

for each pill or capsule. It may be dissolved in vaseline, fifty per cent., and given hypodermatically. It may also be used by Bergeon's method of rectal injections, the carbonic acid gas serving as a vehicle. It is indicated where turpentine has been given, especially in bronchitis.—*Revue Générale de Clinique et de Thérapeutique*, June 2, 1887.

Extirpations of the Larynx.—In the *Deutsche medicinische Wochenschrift* of June 2, p. 470, Dr. Eugene Cohn reports some additional operations by Dr. Hahn, and sums the results of the nine previous total extirpations by that surgeon, reported in Volkmann's *Klinische Vorträge*, Heft 260. The new cases are as follows:

I.—Shoemaker, aged sixty, from whose larynx several portions of carcinomatous tissue had been removed laryngoscopically, the tumor augmenting meanwhile, and becoming perceptible externally. The tumor involved both vocal bands and portions of the arytenoid and thyroid cartilages. Feb. 17 a low tracheotomy was done with some difficulty on account of the little space available, and ossification of the cartilages. An iodoformized compressed sponge canula was introduced; the incision was extended up to the hyoid bone, and the larynx was divided anteriorly to ascertain the dimensions of the growth, which extended as far down as the upper two rings of the trachea, and as high up as to involve the epiglottis. The hyoid bone was separated from the muscles of the lower jaw, and then hyoid bone, epiglottis, the entire larynx, and the two tracheal rings were detached from above downward. The hypoglossus nerve and the lingual artery were wounded. Considerable bleeding ensued from the upper corner of the wound, which was repressed with wood-wool tampons, and arrested by ligatures after the detachment of the larynx had been completed. The wound was tamponed with iodoformed gauze, and covered lightly with carbolized gauze. The patient coughed several times directly after the trachea had been opened, and an extensive emphysema ensued, reaching from the middle of the chest up to the eyes. Rigor occurred on the fourth day; facial erysipelas developed from the nose, and extended the next day over both cheeks. Death on the eleventh day. Autopsy: Erysipelas faciei et capitis; tracheitis et bronchitis; pneumonia catarrhalis.

II.—May 29, 1886. Tradesman, aged fifty-one. Dysphagia of a year's duration; hoarseness; dyspnœa; weakness. Intralaryngeal treatment had been of no avail. A grayish, irregular tumor beneath the epiglottis, on the left side, nearly occluded the larynx. Low tracheotomy, insertion of the iodoformed sponge canula, and incision, as above. Exposure of the larynx and laryngo-fissure. The tumor extended into the upper end of the trachea. The larynx was severed just above the cricoid cartilage and then detached, in part with the thermocautery, from below upward, together with the epiglottis and the hyoid bone. The extirpation was completed by removing the cricoid cartilage and the two upper rings of the trachea. The œsophagus was stitched to the skin. Moderate bleeding, arrested

with wood-wool tampon. Dressings in case I. The course of the case was remarkably good. On the second evening only the rectal temperature reached 38.8. The sputum was not bloody, even directly after the operation. The tampon canula was changed for an ordinary one in twenty-four hours. The general well-being was not disturbed, respiration through the canula was free, and there was only a slight bronchial catarrh. The patient was fed twice a day through the tube; and was quite late—six weeks—learning to swallow first solid, and then fluid nourishment. About the same time an artificial larynx was introduced, and the patient learned to speak with it so as to be understood.

August 11th dismissed from the hospital. In November the patient wrote that he had severe pain in swallowing and distressful salivation. In March, 1887, he wrote that his sufferings had increased, and that for some months he had been conscious of a hardening in his throat, which had increased very much. He was so ill that he dreaded to leave his home. In this case, therefore, there had been recurrence in all likelihood.

III.—Man, æt. fifty-four, hoarse for a year. An irregular, grayish tumor, imbedded in nearly the whole left vocal band, and microscopically a cornifying cancroid. Tracheotomy, tamponade, laryngo-fissure; extirpation of left half of larynx, except the cricoid cartilage. Course normal. This is Semon's case, *Brit. Med. Journ.*, No. 1351.

IV.—In this instance a proposed extirpation was found unnecessary at the time. A merchant, æt. thirty-seven, relieved several times of dyspnœa from a small laryngeal tumor, by intralaryngeal evulsions; but the last operation, three days before, had given no relief. Operation immediately on entrance. High tracheotomy; tamponade; laryngo-fissure. A hard, circumscribed tumor, ulcerating superficially, reached as far as below the right vocal band. The tumor was so superficially implanted, and so circumscribed, that laryngectomy seemed unnecessary, and the ulcerating mass was scraped out and the parts seared with the thermo-cautery. Iodoform tamponade of the wound. The canula was changed for an ordinary one on the next day, and this was permanently removed on the twentieth day. On the thirty eighth day the patient was dismissed with free respiration, and a good, though hoarse, voice. Recurrence in the same locality, three months after operation. Partial resection of the larynx may become necessary.

Concerning the subsequent history of Hahn's nine previous total extirpations for carcinoma and sarcoma, two are dead from recurrence—one six months, the other (sarcoma) four months after operation. One, operated on in 1880, still lives, seventy-five years of age, is hearty, and speaks with an artificial larynx. Another is living, but has had recurrence. Of the entire ten cases of total exturpation, four died within a few weeks—one of erysipelas, one of mediastinitis, one of pleuritis and pulmonary gangrene, and one of pneumonia.

Of the four partial resections none died from the results of the operation. Two of these were for carcinoma. In one there was recurrence within four months, and then the exturpation had to be made complete.

REVIERE'S SEDATIVE POTION.—DR. GENEUIL suggests the following modification of this well-known and valuable officinal preparation where there is vomiting, accompanied and caused by hepatic or enteric pains:

R.—Hydrochl. of morphine	. . .	gr. j.
Cherry laurel water	. . .	℥ijss.
Sulphuric ether	. . .	℥j.
Water to make	. . .	℥vij.

Mix, dissolve, and divide into two equal parts. To the first add one drachm of bicarbonate of potassium and one ounce of syrup of orange flowers. To the second add one drachm of citric acid and one ounce of aromatic syrup of citric acid (flavored, if desired, with essence of lemon). A tablespoonful of each mixture to be administered (by itself) every five minutes until relief is obtained. The alkaline syrup should be given first. If the pains are not very severe, or the patient be very nervous, the morphine may be replaced by double the indicated quantity (or two grains) of codeine.—*Technics*, May 17, 1887.

PEPTONES IN THE BLOOD AND URINE.—GEORGES is quoted by the *American Journal of Pharmacy* for May, 1887, as giving the following methods:

1. This has been recently employed by Wassermann for the detection of peptones in the blood. The blood is received in strong alcohol; the clot thrown on a filter is washed first with cold then with boiling water; the aqueous solution is concentrated to about double the volume of the blood taken, and then added to the alcoholic solution; sodium acetate and ferric chloride are now added to the liquid. After filtration and cooling, the last traces of albumen are removed by adding potassium ferrocyanide and acetic acid, filtered, the excess of ferrocyanide precipitated by copper acetate, filtered, excess of copper removed by hydrogen sulphide; filtered again, and heated on the water-bath to expel hydrogen sulphide and to concentrate the liquid. This method gives good results, especially if care be taken to neutralize, or even to add any slight excess of alkali on adding the sodic acetate and ferric chloride. It also serves very well for the investigation of peptones in urine, commencing by boiling to precipitate albumen coagulable by heat, and terminating as above.

2. The double iodide of potassium and mercury precipitates albumen and the peptones, and Tanret has shown that the albuminous precipitate is insoluble in boiling acetic acid, whilst the peptone precipitate dissolves completely. Employing these reactions, Georges has established a much more rapid method as follows: Precipitate by heat all the coagulable albumen; treat the urine with acetic acid and the double iodide, wash the precipitate on a filter with cold water charged with acetic acid to the same extent as the urine; wash again with the same acidified water boiling, keeping the washings apart. The clear liquid obtained gives a precipitate on cooling if the least trace of peptonic precipitate has been dissolved. It is only necessary to neutralize in order to obtain a solution to which the double iodide test can be applied.

USEFUL PREPARATIONS OF IODOL.—DR. WOLFENDEN, of London, mentions in the *Practitioner* for May, 1887, the following as preparations which he has found useful:

1. *Powder of Iodol.*—The pure powder may be used.

There is no need to mix it with starch or sugar, etc., since, being fine, it is readily dusted over a raw surface, or insufflated into the throat. Possessing no toxic power, it is of more importance to cover the diseased surface than to measure the dose. For all laryngeal, pharyngeal, and most nasal and oral conditions this is, perhaps, the most generally useful application.

2. *A solution in Alcohol and Glycerine.*—This was Mazzoni's original application: iodol, 1 part; alcohol, 16 parts; glycerine, 34 parts. This forms a good application by means of the brush, or may be used as a very coarse spray.

3. *Iodol*, 1 *drachm*; *Ether*, 1 *ounce*.—This forms a clear brown solution, useful for application either by the spray or brush. The ether quickly evaporating leaves the powder *in situ*. It is useful for naso-pharyngeal atrophic conditions.

4. *Iodol*, 1 *drachm*; *Glycerine*, 1 *drachm*; *Vaseline*, 7 *drachms*.—This is a modification of one of Rumbold's sprays. It is a very soothing application for pharyngeal conditions. It requires to be warmed before using.

5. *Iodol Pastilles*.—(Iodol, 1 grain; glycerine, 1 minim; glycogelatine, 18 grains.) These are very useful for chronic pharyngeal conditions, and are much preferable to iodoform pastilles.

6. *Iodol Bougies*, containing ½ a grain iodol in each. These are made for use in diseased nasal conditions.

7. *Iodol Wool*, 10 per cent., for tampons, etc.

8. *Iodol Gauze* for dressings.

Laparotomy for Tubercular Peritonitis.—Kümmel, of Hamburg, at the recent meeting of the German Surgical Congress, reported two cases of tubercular peritonitis treated by laparotomy, as follows:

The first was the case of a young woman in whose abdomen encysted dropsy existed, in which the retro-peritoneal glands were found; the cavity was studded with miliary tubercles. The abdominal cavity was disinfected and sutured; perfect recovery followed.

The second case was that of a man, aged twenty, who had ileus after an operation for caries of the os calcis. The intestine was found almost ligated by adhesions. By enveloping the intestine in carefully antisepticized napkins the adhesions were severed, the tissues properly united, and the abdomen closed. Recovery followed, but general tuberculosis followed later.

Kümmel cited 30 cases, of which 25 were well at the time of his report. In 11 cases the diagnosis was confirmed by the microscope.—*Berliner klinische Wochenschrift*, May 23, 1887.

Fournier's Treatment of Scabies.—1. A thorough application of soap, followed by a full bath.

2. Frictions over the body with the following mixture:

Glycerine	2 parts.
Gum. tragacanth.	$\frac{1}{100}$ part.
Flowers of sulphur	1 "
Sodium carbonate	½ "

after which a second bath must be taken; the personal and bed linen should be carefully laundried, and gloves which have been worn should be burned. On the day following, emollient baths and the use of powdered starch, or glycerite of starch will be found useful.—*Les Nouveaux Remèdes*, May 24, 1887.

Results of Treatment for Diphtheria in the Oldenberg Hospital.—Lunin reports 296 cases, of whom 164 died; 57 were treated with sublimate applications 1 to 1000, and washing out the pharynx with 1 to 5000; of these patients the mortality was 43 per cent. In a series of cases treated with resorcine 10 to 100 and irrigations with a solution of 1 to 100, the mortality was 65 per cent.

Pencilling the fauces with lanoline 1 to 10, and irrigation with alcoholic solution of lanoline, 2 to 100, was employed in 28 cases, whose mortality was 53 per cent.

94 cases were treated with ferric chloride, 1 or 2 drops every half hour. The mortality was 56 per cent. In addition the pharynx was irrigated with boric acid solution, 1 to 300. The treatment with bromine water gave a mortality of 69 per cent, and treatment by essence of turpentine, 10 drops every hour, 43 per cent.

The statistics are not sufficient to establish the value of any medicament. Turpentine gave the best results in the fibrinous form and iron in the phlegmonous form. Laryngeal complications were treated by inhalations and a solution of sodium bicarbonate, corrosive sublimate, and apomorphia internally, and, as stimulants, the free use daily of tea and rum.—*Gazette Hebdomadaire*, May 27, 1887.

Cæsarean Section in Holland.—Maasen, of Holland, is reported, in a recent Dutch medical journal, to have performed Cæsarean section on a primipara, a dwarf, the *conjugata vera* of whose pelvis was two and one-third inches. The wounds healed in twelve days, and mother and child made a perfect recovery.

Maasen attributes his success to antisepsis and to having abstained from attempts to deliver by forceps.

Tracheotomy in the Charité Children's Hospital at Berlin.—After eliminating twenty-five children under two years of age, there were, out of 128 cases, 20.4 per cent. of cures for croup, and 18.75 per cent. of cures for diphtheria. It is not necessary to perform the operation after the first attack of asphyxia.—*Journal of Laryngology*, May, 1887.

Buror's Fluid.—This liquid is used where the antiseptic dressings, for any reason, cannot be applied. Its formula, from the Pharmacopœia of Belgium, is as follows:

Crude alum	75 gr.
Crystallized potassium acetate	12½ ʒ.
Distilled water	1 quart.

Mix, dissolve, filter.

For external use only.

The Diagnosis of Cancer by the Examination of the Blood.—Hayem has recently read a paper on the leucocytosis accompanying the development of neoplasms. A cubic millimetre of blood should yield normally 6000 white blood-corpuscles, but the numerical fluctuations are greater for white than for red blood-corpuscles. Hayem, assisted by M. Alexandre, draws the following conclusions: Scirrhus and encephaloid cancers are accompanied by a slight increase in the number of white blood-corpuscles. The leucocytosis is much more marked with osteo-sarcoma and lympho-sarcoma.

Epithelioma has the least influence in inducing an increase in the white corpuscles. Hayem believes that the leucocytosis may prove of diagnostic service, and mentions a case of doubtful epithelioma of the foot in which M. Alexandre counted 14,000 white globules per cubic millimetre; it was thought during the life of the patient, from this circumstance and from the absence of inflammatory complications, that the disease might be cancerous. The case terminated fatally after operation, and the necropsy revealed several visceral neoplasms of encephaloid structure.—*Lancet*, June 4, 1887.

Lithotomy in Russia.—At the Second Congress of Russian Surgeons, held at Moscow, Nikolsky reported the results of lithotomy as practised by Russian surgeons. 318 cases of the lateral operation were reported with 30 deaths; 29 median operations with 1 death, and 51 suprapubic lithotomies with 14 deaths. The choice of lithotomy over litholapaxy is accounted for by the fact that these patients commonly seek surgical aid when the calculi have become very large and crushing was impossible.

Nikolsky formulates his indications for the various operations as follows: If the stone be large and smooth, the urine relatively normal, and the surgeon hopes to remove the stone quickly, as well as when the stone is in a pocket of mucous membrane, the suprapubic operation is indicated. When the stone is small in adults, and the urine nearly normal, the median incision is preferred. If the bladder is hypertrophied, the lateral incision is made. When severe cystitis is present, the bladder is treated as an abscess cavity and drained by the lateral incision.—*Centralblatt für Chirurgie*, May 28, 1887.

Phosphorus and its Administration.—Soltmann condemns all aqueous preparations of phosphorus, and recommends the oily preparations, and especially an oily solution of 1 to 500. In its preparation three grains of phosphorus are dissolved in three and one-eighth ounces of oil of almonds over a water bath; when the phosphorus has been previously thoroughly dried and the process is carefully conducted, the phosphorus is never deposited. The physician may order as follows:

℞.—Phosphori . . . . . gr. $\frac{1}{10}$
Ol. morrh. . . . . ʒ 3ss.—M.

Sig.—Daily one teaspoonful, which may be conveniently dispensed by adding five grammes (ʒ $1\frac{1}{4}$) of the almond oil solution of phosphorus to ninety-five grammes (about three ounces) of cod-liver oil.

The following formula may also be employed.

℞.—Phosphori . . . . . gr. $\frac{1}{10}$
Ol. amygdal. amar. . . . ʒ $2\frac{1}{2}$
Aquæ destill. . . . . ʒ 20
Gummi arab. . . . . ʒ $2\frac{1}{2}$.—M.
Ft. emuls.

Sig.—One teaspoonful daily.—*Therapeutische Monatshefte*, May, 1887.

Sterilized Bandage Material.—At the recent meeting of the Society of German Surgeons, Schlange, of Berlin, made some remarks upon materials for dressing wounds, which we summarize as follows: None of the dressings at present used and impregnated with antiseptics, perfectly destroy bacteria in wounds. It has been shown that sublimated gauze, when immersed in blood or hydrocele fluid, permits the growth of bacteria, because the sublimate enters into combination with a portion of the albuminoids, and the bacteria flourish in the remaining albumen, which becomes a culture medium.

Schlange advised the use of dressings as prepared for Bergmann's clinic, by sterilization with hot steam at 100° C., and drying. The impregnation with sublimate is omitted. Such sterilized dressings are placed upon the wound.

Volkmann advised the retention of iodoform as an antiseptic, and described his custom of placing iodoform gauze immediately upon the wound, and over that a peat-bag without any antiseptic substance. Lister's dressing, he thought, was often a fomentation to a wound. He had excellent results with this treatment.

Von Bergmann thought that our study of the treatment of wounds should now be directed to finding a perfectly sterile dressing.

Kohler thought sublimate gauze, for army service in the field, a sterile dressing.—*Berliner klinische Wochenschrift*, May 30, 1887.

A Formula for the Use of Bismuth in the Summer Diarrhœas of Children.—

℞.—Bismuth. subnit. . . . . gr. 10.
Mucilag. trag. . . . . ♏ 20.
Aq. chloroform. . . . . ʒj.

for a child seven months old, every six hours.—Dr. Angel Money, in *Treatment of Disease in Children*.

Poisoning by Pilocarpine.—Dr. A. G. Glinsky, of the Kharkov Alexandrovskaia Infirmary, reports (*Proceedings of the Kharkov Medical Society*, part 1, 1886, p. 109) a case of poisoning by pilocarpine—the first of its kind, according to the writer, in medical literature. A gentleman who had been in the habit of using a solution of pilocarpine as a stimulant for the hair, swallowed a considerable dose of the fluid, instead of a solution of quinine. About five minutes afterward profuse perspiration, first of the face and then of the whole body, set in, together with salivation. These symptoms were speedily followed by dimness of sight, prostration, trembling of the limbs, a sensation of cold, noise in the head, and a general sense of confusion. On seeing the patient, about an hour after the accident, Dr. Glinsky found profuse, cold, clammy sweat in big drops on the face and body, coldness of the limbs, slight cyanosis of the hands and lips, a subnormal temperature, pulse 84, full, dicrotic, respirations 14, profuse salivation, great contraction of the pupils, spasmodic shiverings, general restlessness, extreme weakness, and trembling of the lower extremities. The treatment consisted of the internal administration of tannin, and emetics, together with the hypodermatic injection of atropine ($\frac{1}{30}$th of a grain, given in three doses). A quarter of an hour after the injections a striking improvement took place; the perspiration ceased, the pupils became dilated, and tremor disappeared, and on the following day the patient was quite well.—*British Medical Journal*, May 21, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE. . . . . $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 16, 1887.

THE TREATMENT OF SYPHILIS BY HYPODERMATIC INJECTIONS OF MERCURY.

NOTWITHSTANDING the fact that this method of treating syphilis has been before the profession almost ever since the introduction of the hypodermatic use of drugs by Alexander Wood, of Edinburgh, in 1857, it is only within the last year or so that it has in reality received much attention. In 1861, Hebra used injections of corrosive sublimate in the treatment of a papular syphilide occurring in a woman of twenty-one years with success (*Allgem. Wiener med. Zeitung*, 1861, No. 30), but it was not until 1864 that calomel was used in this manner, suspended in a gummy liquid, in the proportion of one-third to one-half of a grain of calomel to twenty-five minims of water or glycerine by Scarenzio, whose report may be found in the *Annales Universelles de Médecine*, 1864.

Berkeley Hill, Ambrosoli, Ricordi, and Montefork, the first in the *Lancet*, in 1866, the last in an inaugural dissertation at Marburg, in 1869, were the next observers to record their experiences with this method, and since then the number of observers has increased to such an extent as to render an attempt at any further historical sketch impossible. Suffice it to say that till lately corrosive sublimate has been much more generally used in this manner than has its more insoluble sister salt calomel, although for some unknown reason the latter preparation seems to be the favorite just at present. Within the last few months a larger number of papers have appeared on this subject than have usually come out in several years. ZEISSL, in the *Centralblatt für die Gesammte Therapie* for June, 1887, gives a very interesting sketch of the use of mercury in this manner, both historical and therapeutical, and another equally interesting paper appears in the *Gazette médicale de Paris* for 1887, Nos. 22 and 23, in which the use of calomel is alone considered.

It at once becomes evident to the thoughtful physician that calomel is, to say the least, a most unfavorable variety of remedy for such a use owing to its insolubility, whereby it is liable to cause inflammation or abscess more rapidly than a systemic influence, and this theoretical deduction has, to a certain extent, proved practically true, although the occurrence of well-developed abscess has been comparatively infrequent, the percentage of their occurrence varying from fourteen to four per cent. of all the cases treated. This variation in the frequency of abscess under this treatment may, of course, have many factors back of it, the most important being cleanliness and the character of the vehicle used by the different observers. The general opinion seems to be that vaseline is by far the least irritating and best vehicle used for this purpose, but, nevertheless, inflammatory conditions are common sequences of its use and come on with sufficient frequency to prevent its general employment.

Other vehicles for administering calomel in this manner have been saline solutions, made by the addition of common salt to distilled water in the proportion of five parts of salt and fifty of water, but the results have been still less favorable. If we consider for one moment the fact that calomel is, when taken internally, dissolved by the gastric acid and then precipitated by the alkaline juices of the intestines, it at once becomes clear that in its injection into the connective tissue it meets no acid, but rather an alkali, and remains undissolved to a very great extent by the juices of the surrounding region. Practical experience has shown, however, that salivation may be produced by its hypodermatic use, thereby proving that it is to some extent absorbed.

The use of corrosive sublimate by the subcutaneous method is hardly more sensible than the corresponding use of calomel, for although it is nonsoluble and less apt to act as a passive foreign body, it is far more irritating. The same chemical objection also obtains here, namely, the fact that an acid salt is to be brought in contact with alkaline juices, and there seems to be no more reason for making such a combination hypodermatically than there is for so doing in a prescription for internal use.

The advantages accruing from such a line of treatment are not readily perceived, and when at last they are discovered are so small as compared to the disadvantages as to lose all weight. Of course, cures and favorable results have been obtained from such practices, as is often the case, be the remedy what it may; but the very fact that this method has remained comparatively unused, except as an ex-

periment for so many years, is at least a good example of the common sense of the medical profession in general, and should prevent the physician from putting into execution any such procedure unless some peculiar chain of circumstances renders it necessary, as in the case of localized gummata situated in dangerous but yet readily approached positions, the rapid breaking down of which may prolong or save life.

CARDIAC DYSPEPSIA.

For a long time it has been recognized that various forms of cardiac disorder, such as palpitation, irregular action, intermittence, syncope, and even angina, may be due to an irritation reflected from a diseased gastric mucosa. It is only of late, however, that cardiac disease has become a recognized factor in the production of gastric disorder. The two conditions, cardiac and gastric disorder, whether functional or organic, are almost invariably associated, and it is a difficult, and often an important, problem to decide which of them is primary. An attempt to render this easier has been made by Dr. Solaro, in *La Medicina Contemporanea*, for March, 1887, who takes as the text of his discourse the Paris thesis of Müller for 1886.

According to Solaro, three types of cardiac dyspepsia may be recognized: 1. A nervous form in which pain is the principal element. The pneumogastric is tender in its accessible points, and there are frequent attacks of gastralgia and pyrosis. As the case progresses the par vagum becomes exhausted, the muscular tunic of the stomach loses its tonicity, and the viscus is in a state of permanent dilatation. This variety is observed in cases of angina pectoris, in exophthalmic goitre, and, in general, in those cardiac diseases in which the nervous element predominates.

2. An anæmic form, distinguished by pain which is acute but fugitive. The digestive functions are accomplished slowly but, in comparison with the former variety, satisfactorily. This form is peculiar to aortic lesions, stenosis, and insufficiency, in which there is either a continual diminution of arterial pressure (stenosis), or the organs are intermittingly supplied with arterial blood (insufficiency).

3. A congestive form in which, while the pain is less severe, the functional disturbances and the lesions of the stomach are much more pronounced. This variety depends upon lesions of the mitral valve, and upon those of the right heart.

It is only in the latter form that typical alterations of the stomach are encountered. The organ is usually dilated, and its walls thickened and congested. The mucosa is covered with a grayish, transparent mucous, or, in more severe cases, with a whitish, pultaceous exudate, resembling a diphtheritic false membrane. This being removed, the mucosa is red, infiltrated with serum, suffused with extravasated blood, or riddled with a multitude of minute erosions. The veins are varicose, and more or less dilated. Many of the peptic glands are atrophied, and their cells filled with fat granules. Atheroma of the gastric arteries is encountered, especially in those cases in which the same lesion exists in the aorta.

The disastrous effect upon nutrition of these secondary gastric changes is manifest without recalling the fact that the only possible *raison d' être* of several fatal cases of pernicious anæmia had been found in similar lesions.

In the treatment of cardiac dyspepsia the pathogenesis of each variety is to be borne in mind. In all three forms the ordinary eupeptics are indicated, while in those of nervous origin, washing out the stomach has been found to be an excellent sedative. In the second and third varieties the remedies are to be chiefly addressed to the heart, the *fons et origo mali*. In the anæmia of heart disease, the *cachexie cardiaque* of French writers, good results have been reported from the use of arsenic.

THE PROGNOSIS IN THE CROWN PRINCE'S CASE.

As we stated last week, the latest professional reports of the condition of the larynx of the German Crown Prince are not at all indicative of malignancy; and now, in view of the apparent success of the operative treatment, the question as to the liability to recurrence of the growth becomes of the greatest interest. In our opinion the commonly estimated ratio of recurrence of papilloma in the larynx is far too high, and many so-called cases we believe are simply recrudescences of fragments of imperfectly removed growths. As a rule a patient, especially if away from home, passes from under treatment as soon as possible after obtaining relief from the malady for which he sought advice; and often, in cases of papilloma, with remnants of the growth unremoved. Hence it is of importance to keep a patient under observation for several weeks after the cessation of operative procedures.

Fresh growths, however, are liable to occur in a larynx, which has been previously the seat of papilloma, just as the earlier growths did in the first place. This does not often happen unless the individual is extremely careless in exposing himself to cold, or in over-using his voice especially when hoarse—conditions that aroused the morbid activity which culminated in the original growth. For these reasons we are inclined to believe that, under proper supervision, and with the exercise of ordinary prudence as to exposure and the use of the voice, neither recurrence of the old growth nor development of a new growth in a fresh location is to be feared in a

larynx carefully freed from papilloma and kept under observation for a reasonable period thereafter.

SOME PHYSICAL DIFFERENCES BETWEEN MEN AND WOMEN.

IN an article upon the "Mental Differences between Men and Women," which lately appeared in *Nineteenth Century*, GEORGE J. ROMAINES claims that, as the average brain-weight of women is about five ounces less than that of man, on merely anatomical grounds we should be prepared to expect a marked inferiority of intellectual power in the former. This difference, he states, is proportionally greater than that between the female and male organism as a whole, and is largely affected by the grade of civilization, being least in savages.

Upon the authority of Sir J. Crichton Browne, he strengthens this view as to the brain inferiority of the female, by the further statement that from investigations now being made by the latter, not only is the gray matter of the brain less deep in the case of the female than it is in that of the male, but also receives less than a proportional supply of blood. For these reasons, and also because the differences begin in embryonic life, Browne regards them as "constituting a fundamental sexual distinction, and not one that can be explained on the hypothesis that the educational advantages enjoyed either by the individual man or by the male sex generally through a long series of generations, have stimulated the growth of the brain in the one sex more than in the other."

As is well known, the differences between the male and the female pelvis, the latter indicating very clearly its adaptation to childbearing, are very obvious, so that the two, when typical forms are observed, may be readily distinguished.

Here, too, there is a corresponding fact to that stated as to the relative difference between the brain of man and that of woman, this difference being less marked in savage races, for in the pelves of the lower races the sexual characteristics are less obvious; that is, the male and female pelvis resemble each other more closely. In some instances this resemblance is so great that it is difficult to distinguish between the two.

Romaines attributes the mental differences between men and women to the Darwinian principle of selection, both natural and sexual, by the one being meant the contest between rival males, and by the other success in the general struggle of life; and, using the words of Darwin: "as in both cases the struggle will have been during maturity, the characters gained will have been transmitted more fully to the male than to the female offspring."

But conceding this as the explanation of the larger brain of the male, and hence the greater mental power, how is the pelvis of the female made to differ more strikingly from that of the male in the advancement of a race? Its final cause is quite obvious, for with a greater brain development there is corresponding increase in the size of the cranium, and there must necessarily be a larger bony birth canal through which it is to be transmitted. Its active cause may have been sexual selection, the successful male selecting the female whose general form, including that of the pelvis, differs most decidedly from that of the male, until in long generations and with the higher development of civilization the original difference becomes more marked until finally the typical female pelvis is produced.

THE Coroner of Philadelphia held an inquest last Monday on four of the cases of poisoning from eating buns colored with chrome yellow, to which practice public attention was first called by THE MEDICAL NEWS, six months ago. The use of chrome yellow to give a rich egg color to the cakes sold by the baker was proved, and the evidences of lead were found on chemical analysis in the viscera. The jury rendered a verdict, "That the deaths, in their opinion, were undoubtedly due to chronic lead poisoning, and that the poisoning resulted from the use of chromate of lead as a coloring matter in buns and other breadstuffs." The Coroner thereupon held the baker, in whose own family there had been six cases of poisoning from this cause, to await the action of the Grand Jury.

Suits to recover damages for sickness, suffering, and death have also been begun against several parties who are charged with adulterating, and causing to be adulterated, buns and cakes, and selling, and causing to be sold, "adulterated articles of food colored with injurious, fraudulent, and poisonous coloring matter."

IN another column we present an abstract of the report of the British Hydrophobia Commission, which constitutes the ablest defence of M. Pasteur's method which has yet been made, and it is a cause for congratulation that men so competent to observe facts and weigh evidence have been able, after full investigations, to reach a unanimous conclusion as to the prophylactic value of the inoculations of Pasteur.

THE anxiously-looked-for autobiography of the late DR. SAMUEL D. GROSS has just been issued from the press of George Barrie, in two very handsome octavo volumes, of over 400 pages each. The work treats of the men and times of Dr. Gross's long and active professional life, and cannot fail to prove of deep interest to a large circle of readers. We shall review it at an early day.

THE American Neurological Association will meet at the West End Hotel, Long Branch on July 20th, 21st, and 22d, under the Presidency of Dr. Landon Carter Gray, of Brooklyn.

THE yellow fever is reported to be slowly increasing at Key West. Last Saturday there were five new cases and two deaths. On Tuesday there were the same number of new cases and one death. The record to July 10th stands: Total cases, 83; deaths, 27; sick at present, 33; discharged cured, 23.

A temporary refuge station is being established by the Marine-Hospital Service at Egmont Key, where ten days' detention will be required, and disinfection of baggage will be carried out.

DOCTOR HENRY CARPENTER died at Lancaster, Pa., on July 9, 1887, aged sixty-eight. He was the fifth physician in a family of recognized ability in medicine and politics, and was one of the first students who matriculated at the Pennsylvania Medical College. After graduation he practised his profession at Lancaster, where he proved a skilful surgeon, obstetrician, and general physician. He was especially versatile in his talents, and combined good mechanical ability with excellent judgment. Both previous to and during the war of the Rebellion he rendered the Government valuable professional services.

Dr. Carpenter was also actively interested in politics, and in the development of the mercantile interests of his home; and his position in the community in which he lived was one of honor and influence.

REVIEWS.

EVACUANT MEDICATION. By HENRY M. FIELD, M.D., Professor of Therapeutics, Dartmouth Medical College, etc. Philadelphia: P. Blakiston, Son & Co., 1887.

THIS book is a concise *résumé* of the notes of extensive clinical observation as prepared for lectures, supplemented by study of the current literature of the subject. The author's purpose was "to provide a practical study of the individual action, application, and contra-indications of the more prominent cathartic agencies;" and this has been accomplished in a clear, forcible, and practical manner.

Among the many points of interest presented, we notice the endorsement of the commonly received doctrine of the emmenagogue properties of aloes; and the successful treatment of gonorrhœa by the vinous tincture of colocynth. The distinction between cathartics and cholagogues is sharply drawn, and the fact that hydragogues are depressants of bile formation is emphasized. The use of calomel receives the critical discussion which its importance justifies, and its position and dosage as a cholagogue are clearly defined.

A number of convenient formulæ are given, of which we quote the following, as valuable in administering castor oil in the treatment of dysentery:

R.—Ol. terebinth.	. . .	gtt. 80.
Ol. cinnamon.	. . .	♏ 5.
Ol. ricini	. . .	ʒ 5.
Mucil. acaciæ	. . .	q. s.
Syr. simpl.	. . .	q. s.
Aq. puræ	. . .	q. s. ad ʒ 2.

Sig.—Shake thoroughly. One teaspoonful, repeated as needed.

The author's presentation of emetic medication, and also "super vomition," is suggestive and valuable; the omission of cocaine from the remedies advised for obstinate emesis is, however, noticeable.

No remedies are more commonly used and abused than evacuants, and books of the practical value of Dr. Field's cannot fail to interest and serve the profession.

CORRESPONDENCE.

LETTER FROM MUNICH.

The Royal University—Laparotomy in Rupture of Uterus—Osteomalacia—Use of Anæsthetics—A New Work on Obstetrics.

THE number of students in the Royal University here is 3389. The medical department has 1186; of these, only 508 are Bavarians, the relative proportion of the foreign element marking well the reputation of the school. I saw two Japanese, and found several Americans among them.

Having seen in the report of the obstetrical department a number of cases of rupture of the uterus, and no laparotomies mentioned in connection, I inquired as to this point, and learned that there had been no case since Prof. Winckel took charge in which the circumstances justified the operation. This measure is fully recognized, and he has performed laparotomy for ruptured uterus three times, all the cases successful. The pelvis of one is in his collection, and is a most interesting specimen of osteomalacia. The professor and his father were about to perform the Cæsarean section when the rupture took place, and the laparotomy followed immediately. The patient lived fourteen years afterward.

There was an interesting case of osteomalacia in the wards. Patient, aged thirty-seven, had had eight children, the last several years ago. The pelvic deformity had advanced to such a degree that the finger could scarcely be passed between the rami of the pubes up to the symphysis. She was in bed, and having constitutional treatment.

In regard to anæsthetics. So far, chloroform alone has been seen here, and I am informed that this is the only anæsthetic used throughout Germany, except at Vienna, where Billroth uses a mixture of chloroform and ether. I can learn of no accidents, and when they were inquired for, the opinion seemed to be that they might and did occur under all anæsthetics, while chloroform presented great practical advantages over the others. Prof. Winckel expressed much dissatisfaction at what he witnessed of ether administrations during his visit to our country. Administration of chloroform here is by means of a small wire mask, just large enough to cover mouth and nose, over this is stretched a layer,

perhaps two, of some light material, and upon this the liquid is dropped or sprinkled. It is an unexceptionable method; first, negatively, air cannot be shut out from the patient; second, positively, it insures complete mixture of the vapor with air. This cannot be said of the administration by a towel upon which chloroform is poured, and there is no doubt that that mode of administration is one factor in causing fatal accidents. In one case in which there was a good deal of embarrassment to the respiration, the administrator bent the patient's head backward, and elevated the lower jaw by placing his fingers behind the rami.

The injection of narcotics a short time previous to the administration of chloroform, is not practised here. I called upon Prof. Nussbaum especially in regard to this point, because his name is connected with the very first steps of this practice. Neither morphia nor atropia, or the two combined, is given here or elsewhere in Germany, so far as I could learn. I was particular to inform myself in regard to this point, which I firmly believe to be one of the greatest practical value in connection with the administration of anæsthetics.

Prof. Winckel has in preparation, and nearly ready for publication, a new work on obstetrics. An entire new set of illustrations is promised, and those who are acquainted with his photographic illustrations of the pathology of the female sexual organs, will know what may be expected.

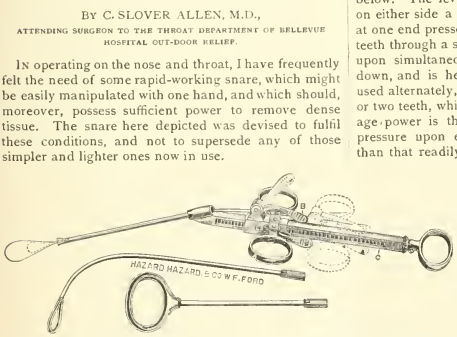
MUNICH, June, 1887.

NEW INVENTIONS.

A NEW SNARE AND ÉCRASEUR.[1]

BY C. SLOVER ALLEN, M.D.,
ATTENDING SURGEON TO THE THROAT DEPARTMENT OF BELLEVUE HOSPITAL OUT-DOOR RELIEF.

IN operating on the nose and throat, I have frequently felt the need of some rapid-working snare, which might be easily manipulated with one hand, and which should, moreover, possess sufficient power to remove dense tissue. The snare here depicted was devised to fulfil these conditions, and not to supersede any of those simpler and lighter ones now in use.



The power employed is not that of the screw, but of the lever, and is applied by means of a double lever, worked alternately by the middle and forefinger. As the instrument is made of steel, it will stand heavy work in operating on other parts of the body. It can be worked perfectly with one hand, while the other holds the speculum or mirror, and no part of the instrument or hand interferes with a clear view of the part operated on. The wire loop can be quickly and firmly contracted around the base of the tumor, and then, without delay, great power can be applied, and the tissue cut through as rapidly or as gradually as desired. The ends of the wire are quickly fastened or released by the simple movement of a lever, and will not slip. The laryngeal and post-nasal tubes can be inserted at different angles, so that the hand can be held in the most convenient position for working. The instrument is especially adapted for operations where rapid work is called for. The ends of all the tubes are flattened, so as to keep the wire loop from twisting, and to enable the operator to know its exact position. After cutting through, the slide can be released and pushed up to its former position by pressing back the catches on either side with the thumb and forefinger.

The different parts of the snare are not very clearly shown in the cut. The square shaft (*C*) is of steel, having at its upper end a socket for the insertion of the tubes, while at the lower end is a swivel thumb-ring. On either side of the shaft is a line of ratchet-teeth, which are countersunk, so as to allow the square tube to slide freely upon the shaft. Upon the upper part of this square tube there is a device for fastening the ends of the wire. It consists of a lever attached to an excentric, beneath which the wire passes when the lever is raised. When the lever is depressed (as shown at *B*) the wire is firmly pressed down upon the slightly roughened bed-plate. Strain upon the wire tends only to draw the lever down tighter, so that the wire will break before slipping. The two rings (*A*) are connected by a double lever which, at the centre, loosely surrounds the square tube or slide, and is pivoted to it above and below. The lever rotates on these pivots, and carries on either side a ratchet catch, pivoted in the arm, and at one end pressed down by a spring against the ratchet teeth through a slot in the slide. If the rings are pulled upon simultaneously, the wire may be quickly drawn down, and is held by the ratchet. If the fingers are used alternately, one ratchet is drawn down over one or two teeth, while the other holds fast. A great leverage power is thus exerted upon the wire. A slight pressure upon either ring develops a power greater than that readily obtained in instruments in which the screw is used.

The lower figure in the cut represents a modification for the removal of the tonsil. It consists of a split ring, between the sides of which the wire is concealed, and held in place by small projections. The ring having been pressed over the tumor in the usual way, traction with the fingers, exerted simultaneously upon the two arms of the lever, quickly draws the loop from the cleft of the ring and contracts it upon the tumor; then alternate traction will cause the wire to cut through. The proceedings can be easily watched. Steel piano wire, No. 5, is the smallest that can be used for this heavy work, and is the size best adapted to the instrument for general work. There are similar attachments for the larynx and vault of the pharynx. These split rings are of various shapes, and are placed upon the tubes at different angles. The instrument is especially useful in operating on tumors of the larynx.

NEW YORK, 21 EAST TWENTY-EIGHTH STREET.

[1] Exhibited before the Laryngeal Section of the N. Y. Academy of Medicine.

NEWS ITEMS.

The Report of the British Commission of Inquiry into M. Pasteur's Treatment of Hydrophobia.—The report of the Commission appointed last year by the President of the Local Government Board to inquire into M. Pasteur's treatment of hydrophobia was presented to Parliament last week. The Commission consisted of Sir James Paget (Chairman), Sir Joseph Lister, Sir Henry Roscoe, Dr. Richard Quain, Dr. Lauder Brunton, Professor Burdon Sanderson, Dr. George Fleming, and Mr. Victor Horsley (Secretary), and they all signed the report, an abstract of which appears in *The Lancet* of July 2d.

The report commences by stating that it was found necessary that some of the members of the committee should, together with Mr. Victor Horsley, the secretary, visit Paris so as to obtain information from M. Pasteur himself, to observe his method of treatment, and investigate a considerable number of cases of persons inoculated by him; and, further, that a careful series of experiments should be made by Mr. Horsley on the effects of such inoculation on the lower animals. Mr. Horsley's experiments are stated to confirm entirely M. Pasteur's discovery of a method by which animals may be protected from the infection of rabies. If a dog, rabbit, or other animal be bitten by a rabid dog and die of rabies, a substance can be obtained from its spinal cord which, being inoculated into a healthy dog or other animal, will produce rabies similar to that which would have followed directly from the bite of a rabid animal, or differing only in that the period of incubation between the inoculation and the appearance of the characteristic symptoms of rabies may be altered. The rabies thus transmitted by inoculation may, by similar inoculations, be transmitted through a succession of rabbits with marked increase of intensity. But the virus in the spinal cord of rabbits that have died of inoculated rabies may be gradually attenuated by drying the cords, so that after a certain number of days' drying it may be injected into healthy rabbits or other animals without any danger of producing rabies; and by using on each successive day the virus dried during a period shorter than that used on the previous day an animal may be made almost certainly secure against rabies, whether from a bite or from any method of subcutaneous inoculation; and this protection is proved by the fact that if animals so protected and others not thus protected be bitten by the same rabid animal, none of the first set will die of rabies, and, with rare exceptions, all of the second set will succumb.

It may hence be deemed certain that M. Pasteur has discovered a method of protection from rabies comparable with that which vaccination affords against infection from smallpox. It would be difficult to over-estimate the importance of the discovery, whether for its practical utility or for its application in general pathology. It shows a new method of inoculation, or, as M. Pasteur sometimes calls it, of vaccination, the like of which it may become possible to employ for protection of both men and domestic animals against others of the most intense kinds of virus. The duration of the immunity conferred by inoculation is not yet determined; but during the two years that have passed since it was first proved there have been no indications of its being limited. The preventive treatment adopted by M. Pasteur is based on the foregoing experience; but the determination of the success of the method is far from easy, owing to (1) the difficulty of determining whether the bites were really those of rabid animals; (2) the probability of hydrophobia in persons bitten by dogs that were certainly rabid depending very much on the number and character of the bites, whether they were on exposed parts or parts protected by clothing; and in all cases in the amount of bleeding; (3) in all cases the probability of infection may be affected by speedy cauterizing or excision of the wounded parts, or by various washings, or other methods of treatment; (4) the unequal danger of bites of different species of animals, and even of different dogs. In some groups of cases the percentage of deaths among persons bitten by dogs believed to have been rabid has been estimated at only 5 per cent., in others at 60 per cent.; and the mortality from the bites of rabid wolves has been variously estimated at from 35 to 90 per cent.

By the courtesy of M. Pasteur the committee were enabled to investigate personally ninety cases treated by him, these being mostly those which had been earliest treated, in which the periods since inoculation were longest, and living within reach in Paris, Lyons, and St. Etienne. Among the ninety cases there were twenty-four in which the patients were bitten on naked parts by undoubtedly rabid dogs, and the wounds were not cauterized or treated in any way likely to have prevented the action of the virus; there were thirty-one in which there was no clear evidence that the dog was rabid; others in which the bite had been inflicted through clothes. It is estimated, from experience of the results of bites in other cases, that had they not been inoculated, not less than eight among these ninety persons would have died. Not one of them has shown since the inoculation any signs of hydrophobia.

Since, in order to quiet fears, M. Pasteur has been obliged to inoculate many in whom there was no satisfactory evidence that the bite was that of a rabid animal, it might be unjust to estimate the total value of his treatment in the whole of his cases as being more than the rate of mortality observed in them compared with the lowest rate observed in any large number of cases not inoculated. This lowest rate may be taken at 5 per cent.; and, as between October, 1885, and the end of December, 1886, M. Pasteur inoculated 2682 persons (including 127 from this country), the mortality should have been 130. But at the end of 1886 the number of deaths was 31, including 7 bitten by wolves, in whom the symptoms of hydrophobia appeared while they were under treatment; in fact, the actual percentage mortality was between 1 and 1.2, showing, on the lowest estimate, the saving of not less than 100 lives. Of 233 persons bitten by animals in which rabies was proved, only 4 died. Without inoculation at least 40 would have died. Among 186 bitten on the head or face by animals in which rabies was proved, only 9 died, instead of at least 40. Of 48 bitten by rabid wolves, only 9 died, instead of nearly 30. Between the end of last December and the end of March M. Pasteur inoculated 509 persons bitten by animals proved to have been rabid; only 2 have died, one of these, bitten by a wolf a month before inoculation, dying after only three days'

treatment. The committee think it therefore certain that the inoculations practised by M. Pasteur have prevented the occurrence of hydrophobia in a large proportion of those who, if they had not been so inoculated, would have died of that disease. And his discovery shows that it may become possible to arrest by inoculation even after infection, other diseases besides hydrophobia. His researches have also added very largely to the knowledge of the pathology of hydrophobia, and supplied a sure means of determining whether an animal which has died under suspicion of rabies was really affected with that disease or not.

The question whether the method itself entails risk to health or life is then discussed, the distinction between the ordinary method and the "intensive" method being pointed out. By the first method there is no evidence or probability of any danger to health at all; but after the intensive method, which is practised in only the most urgent cases, deaths have occurred which might possibly be attributed to the inoculations rather than to the original infection. Yet in the worst cases the intensive method is relatively more efficacious than the ordinary method, nor is the rate of mortality greater after the former method than after the latter. Certain cases, one of which is detailed, have, however, excited suspicion from the mode of death. The case related is that of a man bitten by a rabid cat at the Brown Institution, treated by M. Pasteur the next day by the intensive method, continued during twenty-four days, and dying about a month later with symptoms of acute ascending paralysis. The man was very intemperate, and had been exposed to chill while crossing the Channel on his return home. Mr. Horsley proved that his death was due to the virus of rabies, by using a portion of his spinal cord for the inoculation of rabbits and dogs, which died with characteristic signs of paralytic rabies such as usually occurs in rabbits. Yet it is by no means certain that the fatal issue in this and in other cases treated by the intensive method was not due to the original infection. M. Pasteur has, however, greatly modified this plan of treatment, which he employs in none but the most urgent cases.

The final paragraphs of the report, which embody practical suggestions, may be given *in extenso*:

The consideration of the whole subject has naturally raised the question whether rabies and hydrophobia can be prevented in this country. If the protection by inoculation should prove permanent, the disease might be suppressed by thus inoculating all dogs; but it is not probable that such inoculation would be voluntarily adopted by all owners of dogs, or could be enforced on them. Police regulations would suffice if they could be rigidly enforced. But to make them effective it would be necessary (1) that they should order the destruction, under certain conditions, of all dogs having no owners and wandering in either town or country; (2) that the keeping of useless dogs should be discouraged by taxation or other means; (3) that the bringing of dogs from countries in which rabies is prevalent should be forbidden or subject to quarantine; (4) that in districts or countries in which rabies is prevalent the use of muzzles should be compulsory, and dogs out of doors, if not muzzled or led, should be taken by the police as "suspected." An exception might be made for sheep dogs and others while actually engaged in the purposes for which they are kept. There are examples sufficient to prove that by these or similar regulations rabies, and consequently hydrophobia, would be in this country "stamped out," or reduced to an amount very far less than has hitherto been known. If it be not thus reduced, it may be deemed certain that a large number of persons will, every year, require treatment by the method of M. Pasteur. The average annual number of deaths from hydrophobia during the ten years ending 1885 was, in all England, 43; in London alone, 8.5. If as in the estimates used for judging the utility of that method of treatment, these numbers are taken as representing only 5 per cent. of persons bitten, the preventive treatment will be required for 860 persons in all England; for 170 in London alone. For it will not be possible to say which among the whole number bitten are not in danger of hydrophobia, and the methods of prevention by cautery, excision, or other treatment, cannot be depended upon.

THE AMERICAN OTOLOGICAL SOCIETY will hold its twentieth annual meeting at the Pequod House, New London, on the 19th of July. The following papers are announced on the preliminary programme:

1. The Examination of the Power of Hearing, and how to Record its Results. Committee report by Dr. H. Knapp (Chairman), Drs. F. S. Prout and D. B. St. John Roosa.

2. The Successful Removal of an Exostosis from the Auditory Meatus by a New Method. By Dr. C. H. Burnett.

3. Cases Illustrating the Differential Diagnosis between Affections of the Middle Ear and those of the Labyrinth. By Dr. D. B. St. John Roosa.

4. Remarks upon a Case of Cerebral Abscess. By Dr. D. B. St. John Roosa.

5. Suppuration of the Tympanum, occurring in a Patient with Bright's Disease, with Presentation of the Pathological Specimen. By Dr. D. B. St. John Roosa.

6. A Case of Syphilitic Disease of the Labyrinth, exhibiting Remarkable Variations in the Degree of Deafness. By Dr. Samuel Theobald.

7. Desquamative Inflammation of the Middle Ear, with remarks. By Dr. O. D. Pomeroy.

8. Photographic Illustration of the Anatomy of the Human Ear. By Drs. H. L. Morse, and B. Alexander Randall, of Philadelphia.

9. An Efficient Powderblower, with remarks upon the Use of Powders in the Treatment of Diseases of the Ear. By Dr. E. E. Holt.

10. A Case of Rapid and Almost Total Loss of Hearing in a Child, seven years of age; Inherited Syphilis apparently the Cause; Marked Improvement following the Use of the Iodide of Potassium. By Dr. A. H. Buck.

11. An Examination of Fifteen Deaf Mutes, by means of F. A. Maloney's Otophone. By Dr. C. H. Burnett.

12. Excision of the Ossicles of the Drum of the Ear. By Dr. Samuel Sexton.

FOOD ADULTERATION IN NEW YORK.—The New York *World* has undertaken to determine whether the charges as to the adulteration of foods, liquors, and medicines at the present time are with or without foundation in fact.

Edward G. Love, Ph. D., was retained to conduct the

examinations. Purchases were made by men from the *World's* staff and a record kept of the weight and place of purchase. The first report refers to sugar, tea, and coffee, and three hundred different stores in New York city were patronized.

A review of the 300 reports discloses that of the samples of tea, 88 were not adulterated and 12 were adulterated mostly with "lie tea" and foreign leaves; that of the samples of ground coffee 72 were unadulterated and 28 were adulterated mostly with chicory and peas; that of the sugar samples 98 were pure and only 2 adulterated with starch glucose. In all, there were, of the 300 samples, 258 good and 42 more or less bad. As to the weights of the samples those of 270 were correct and 30 were light.—*Sanitary News*, June 11, 1887.

DR. S. D. POWELL.—Dr. Seneca D. Powell has been elected Professor of Clinical Surgery in the New York Post-graduate Medical School and Hospital.

APPOINTMENTS AT UNIVERSITY COLLEGE, LONDON.—Dr. Sydney Ringer has been elected to fill the Professorship of Clinical Medicine made vacant by the death of Wilson Fox. Mr. Victor Horsley succeeds Dr. Bastian as Professor of Pathology.

THE INTERNATIONAL CONGRESS ON ALCOHOLISM.—At Antwerp, which, in 1885, was the scene of the last Congress on this great question of public health, it was arranged that the next should be held this year at Zurich, on September 9th and 10th. The permanent committee are organizing for the occasion an exposition of everything bearing on alcoholism. For example: tables and diagrams of different countries, indicating the consumption of alcohol per head of the population; the proportion of persons annually undergoing imprisonment per one hundred thousand of the inhabitants; the annual proportion of suicides and of lunatics; the annual outlay on alcoholic drinks compared with that incurred for articles of prime necessity; plans of asylums for inebriates; specimens of non-intoxicating beverages; and comparative regulations of the various temperance societies, with statistics of their working.—*Lancet*, June 11, 1887.

POISONING BY ORNAMENTAL BISCUITS IN MELBOURNE.—Several children have suffered from all the symptoms of irritant poisoning lately, after eating ornamental biscuits. These were found, on analysis, to contain arsenic and copper in the coloring matter, and the manufacturers, at the instance of the Central Board of Health, were fined £20 and costs.—*Lancet*, June 11, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JULY 5 TO JULY 11, 1887.

HEGER, A., *Lieutenant-Colonel and Surgeon.*—Ordered to Fort Columbus, New York Harbor, N. Y.—*S. O. 156, A. G. O.*, July 8, 1887.

JANEWAY, J. H., *Major and Surgeon.*—Ordered to Benicia Barracks, as Post Surgeon; also, as Attending Surgeon at Benicia Arsenal, Cal.—*S. O. 156, A. G. O.*, July 8, 1887.

BIRMINGHAM, H. P., *Captain and Assistant Surgeon.*—Ordered to Fort Myer, Va.—*S. O. 156, A. G. O.*, July 8, 1887.

WOODRUFF, C. E., *First Lieutenant and Assistant Surgeon.*—Ordered to Fort Mackinaw, Mich.—*S. O. 156, A. G. O.*, July 8, 1887.

WINNE, C. K., *Captain and Assistant Surgeon.*—Ordered to Fort Wadsworth, New York Harbor, N. Y.—*S. O. 156, A. G. O.*, July 8, 1887.

HOWARD, VALERY, *Captain and Assistant Surgeon.*—Ordered to Fort Abraham Lincoln, Dakota Territory.—*S. O. 156, A. G. O.*, July 8, 1887.

MAUS, L. M., *Captain and Assistant Surgeon.*—Ordered to Fort Schuyler, New York Harbor, N. Y.—*S. O. 156, A. G. O.*, July 8, 1887.

GIRARD, J. B., *Captain and Assistant Surgeon.*—Ordered to Fort Lowell, Arizona.—*S. O. 156, A. G. O.*, July 8, 1887.

POINDEXTER, J. D., *First Lieutenant and Assistant Surgeon.*—Ordered to Camp Poplar River, Montana Territory.—*S. O. 156, A. G. O.*, July 8, 1887.

MACAULEY, C. N. B., *First Lieutenant and Assistant Surgeon.*—Ordered to Fort Gibson, Indian Territory.—*S. O. 156. A. G. O.*, July 8, 1887.

BYRNE, C. B., *Captain and Assistant Surgeon.*—Ordered to Washington Barracks, District of Columbia.—*S. O. 156, A. G. O.*, July 8, 1887.

WILCOX, T. E., *Captain and Assistant Surgeon.*—Ordered to Fort Niobrara, Nebraska.—*S. O. 156, A. G. O.*, July 8, 1887.

LIPPINCOTT, H. *Major and Surgeon.*—Ordered to Fort Union, New Mexico.—*S. O. 156. A. G. O.*, July 8, 1887.

CLEARY, P. J. A., *Major and Surgeon.*—Ordered to Fort D. A. Russell, Wyoming.—*S. O. 156, A. G. O.*, July 8, 1887.

CALDWELL, D. G., *Major and Surgeon.*—Ordered to Fort Assininiboine, Montana Territory.—*S. O. 156, A. G. O.*, July 8, 1887.

TORNEY, G. H. *Captain and Assistant Surgeon.*—Ordered to Fort Robinson, Nebraska.—*S. O. 156, A. G. O.*, July 8, 1887.

REED, WALTER, *Captain and Assistant Surgeon.*—Ordered to Mount Vernon Barracks, Alabama.—*S. O. 156, A. G. O.*, July 8, 1887.

PATYKI, J. H., *Captain and Assistant Surgeon.*—Ordered to Fort Huachuca, Arizona Territory.—*S. O. 156, A. G. O.*, July 8, 1887.

EBERT, R. G., *Captain and Assistant Surgeon.*—Ordered to Fort Custer, Montana Territory.—*S. O. 156, A. G. O.*, July 8, 1887.

PELCHER, J. E., *First Lieutenant and Assistant Surgeon.*—Ordered to Fort Monroe, Virginia.—*S. O. 156, A. G. O.*, July 8, 1887.

GARDINER, J. DE B. W., *Captain and Assistant Surgeon.*—Ordered to Fort Washakie, Wyoming Territory.—*S. O. 156, A. G. O.*, July 8, 1887.

CHAPIN, A. R., *First Lieutenant and Assistant Surgeon.*—Ordered to Newport Barracks, Kentucky.—*S. O. 156, A. G. O.*, July 8, 1887.

FORWOOD, W. H., *Major and Surgeon.*—Ordered to Fort Snelling, Minnesota.—*S. O. 156, A. G. O.*, July 8, 1887.

PERLEY, H. O., *Captain and Assistant Surgeon.*—Ordered to Fort Wayne, Michigan.—*S. O. 156, A. G. O.*, July 8, 1887.

TREMAINE, *Major and Surgeon.*—Ordered for examination by Army Retiring Board, at Governor's Island, New York Harbor, N. Y.—*S. O. 151, A. G. O.*, July 1, 1887.

SKINNER, J. O., *Captain and Assistant Surgeon.*—Granted leave of absence for four months, on surgeon's certificate of disability.—*S. O. 151, A. G. O.*, July 1, 1887.

HARRIS, H. S. T., *First Lieutenant and Assistant Surgeon.*—Will be relieved from duty at Fort Ringgold, Texas, upon the return of Assistant Surgeon W. F. Carter, and will then report to Commanding officer at Fort McIntosh, Texas, for duty.—*S. O. 73, Department of Texas*, June 27, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 9, 1887.

HUDSON, A., *Medical Inspector.*—Detached from the "Trenton," and wait orders.

SCOFIELD, W. K., *Medical Inspector.*—Ordered to relieve Medical Inspector Hudson, on the "Trenton."

ORIGINAL LECTURES.

THE TREATMENT OF SPASTIC PARALYSES.

A Clinical Lecture,
Delivered at the Infirmary for Nervous Diseases, Philadelphia, May 20, 1887.

BY S. WEIR MITCHELL, M.D.,
PHYSICIAN TO THE INFIRMARY.

GENTLEMEN: There are now in the wards five cases, all of which exhibit in various degrees what I am apt to describe as the "lead-pipe leg." By this I mean that the limb resists steadily passive motion, and resists in proportion to the abruptness of the force used. As you flex or extend it the resistance felt is like that offered when you bend a bar or pipe of lead. The patient is powerless to relax the member.

These cases all present, as a rule, the symptom of excessive tendon-jerk from a blow or even a faint tap on the tendon of the quadriceps, or that of the gastrocnemius. The ankle clonus is also easily obtainable, and in extreme instances a clonus of the extensor mass of the leg.

In some of these patients the electrical muscle responses to faradic currents are exaggerated, and in most of them the muscle-jerk caused by a direct blow of a percussion hammer on the side of the hand is too ready and too extreme as compared to the muscle-jerk of health.

We also observe that the tendon-jerk, the clonus, which is only a form of that phenomenon, and the muscle-jerk may in most of these cases of spastic trouble be abruptly increased by reinforcements. These are either motor or sensory. This is only an extreme illustration of a fact easily observable as concerns any of the tendon or muscle-jerks of health. Thus, if in a spastic case we cause the patient to cough or make a grimace or violently shut a hand, or if we pinch him anywhere and we time the blow on the muscle or tendon so as to follow the distant voluntary act or the sensation at a brief interval, the jerk is largely exaggerated, and this reinforcement is greatly larger in the spastic case than in health, and is sometimes a help toward a complete diagnosis.

As a rule, all forms of reinforcement are in proportion to the amount of the knee, or in general terms tendon-jerk. If it be large, so is commonly the reinforcement. If it be lost the reinforcement, if present, is trivial. Both are tests of the muscular excitability and of the integrity of the nervous arc, and also more or less of the relative irritability of certain spinal centres. When we learn more of the tracks followed by reinforcing energy, whether motor or sensory, we shall no doubt find in this evolved symptom an important ally in diagnosis.

The resistance symptom, like others seen in the spastic group, varies in degree, and is due to the fact that in bad cases every effort to bend or extend the limb affected excites the muscle, or centres which control it, and is an extreme indication of that excitability which is seen in the exaggeration of knee-jerk and in clonus. When also the will is used to flex or extend these muscles there is the same result, the opponent muscle, which should relax, does just the reverse thing, and as it is stretched offers a positive resistance, which accounts in a measure for the peculiar gait of those cases in which the spastic state involves both groups of muscles in the legs. When only the flexors or extensors are affected, a rare condition, not well understood as yet, the walk is very peculiar; but as I have no mind to-day to do more than so to introduce the matter as to be able to speak of treatment, I shall not pause too long over the varieties of the disorder.

The spastic state may be due to cerebral disease and secondary degenerative spinal changes, to the extreme degree of this seen in some of the spastic disorders of childhood which are so enduring, to local disorders of the cord, to pressure by growths, or to sclerosis of the lateral columns, and, lastly, we can produce artificially a condition in which clonus is possible, knee-jerks and ankle- and muscle-jerks are excessive, and which will even enable us to evolve the "front tap" of Gowers, never present, according to that able author, except in disease. The condition of excitability described was brought about by Dr. Morris Lewis and myself by combining all the means capable of causing reinforcements, as galvanism to the head, pain, and violent muscular motion. With this combination we get in a degree all the extreme phenomena of spastic cases except the muscular resistances, but these we could hardly hope to find, as the condition of excitation is of necessity brief, and leaves but a moment in which to examine results. Near to the close of an epileptic fit we sometimes have a like state of increased tendon-jerks, capacity to evolve clonus, and even some resistance to flexion, but in a few moments a reverse state may be seen of lowered or abolished reactions. Probably the excitability may be due to the reinforcements caused by the convulsing discharges.

I have no intention here of going deeply into the question of the immediate causes of the spastic state, whether pathological or temporarily induced. It will be answered when we know more of the tracks followed by reinforcing energy, and when we have studied the time required for its effects and are absolutely clear as to whether tendon-jerks and muscle-jerks are due to mere induced muscle states or represent unusually rapid reflexes.

I have brought the matter before you in order to call attention anew to methods of treatment which apply not only to almost all chronic and non-progressive forms of spastic paralysis, but also to the forms seen in childhood or adult life as a consequence of hemiplegia, and associated or not with post-paralytic chorea.

Without now concerning ourselves with remote causes,

and they vary with all of the cases in our wards, let it suffice that the muscles in these people react too easily. Behind the spasm, so to speak, there is very often, but not always, a degree of true want of power, so that if, by bromides and very prolonged massage, you temporarily wear out the spasticity, you find that the patient can no longer stand; you have taken away the spasms which splinted the limb and made the upright state possible. But in many non-active cases, which are chronic and unchanging, there is still volitional control enough to enable the patient to profit by a lessening of the spastic state. You can do little good in progressive cases, but much good in others; and I am glad to give you the lesson with examples of success, because as a rule in the chronic spastic palsies of childhood, either there is reckless tendon cutting and braces and nothing else, or no treatment at all beyond circumcision, which in my large experience has been very rarely of value, and is applied remorselessly at some time, by some one, to nearly all the cases in childhood which I chance to see. True functional spastic states from genital irritation must be most rare.

I have here to-day no illustration of those horrible spastic palsies due to rapidly progressive irritative diseases of the cord. They present for you in an extreme degree all the symptoms I have mentioned, and some which I have not dwelt upon. Massage used gently at first and skilfully increased, is a comforting agent in these advancing cases of painful spastic palsy, but it must be most skilfully used. It is a comfort, and no more. When employed in conjunction with large doses of bromides, it may lessen spasm temporarily.

There is, however, another method of manipulation which has real and permanent utility in an uncertain proportion of spastic cases, and seems to act, in part at least, by rendering the muscles less susceptible to the agencies which over-excite them.

If I place this man, who has excessive knee-jerk, on his face, with the thigh rather overextended, and then flexing the leg on the thigh, strike the patellar tendon, I get a violent response. As I bend the leg the reply lessens, until, at a certain point, it ceases altogether. If, keeping the knee in the same position, I now relax the tension on the quadriceps, by lessening the angle of the thigh to the trunk, the knee-jerk returns; it was, therefore, lost, not because we had mechanically interfered with a favoring position of the tendon, but because when we overstretch a muscle it loses power to react when its fibres are suddenly excited by the abrupt little pull you make on them by a blow on the tendon.

This fact is true of the normal knee-jerk, and of the excessive reaction of a spastic case. A certain amount of tension seems to render a muscle less able to respond to excitation. It is true of a blow, and it is true of electricity, as Dr. Lewis and I have shown. It occurred to me that extreme and frequent extension might lessen more permanently the exaggerated excitability of muscles, and from time to time I have tested this hypothesis. I conclude to-day that muscular extension is of use in all cases of hyper-excitable muscles, but that it does best in the typical spastic palsies of childhood, and in such other forms as are pathologically non-progressive. That the process is in these cases useful is for me now past doubt, and when I say that it is useful, I mean that it distinctly adds to the comfortable locomotility of my patients.

I am by no means sure that the reasoning which led up to the use of this simple method was correct, but sometimes in medicine one walks with measured steps up to a truth, and sometimes one stumbles across it.

The plan I shall here describe is very simple, and may have been described before, and methodically used. Let me add that it helps but does not cure.

Every muscle concerned is to be put twice a day, and over and over in a condition of extreme extension by a series of manipulations easily taught to a strong nurse. An example will save a too elaborate description. The girl I now show you is accustomed to the process, and I shall use her as an illustration both of the means and its resultant value. Her clothes are somewhat in the way. The patient should be so far undressed as not to interfere with extremity of movement.

Placing her on her back, the nurse takes the foot in her lap and moves each toe in flexion and in extension, steadily and to the limit of endurance, and then slowly lets it go back to rest. Next the ankle is flexed to the limit with the knee in extension, then the knee is flexed and the foot carried firmly into prolonged extension; lateral motions follow. The leg is then fixed strongly but with deliberate slowness, the patient being on her face, and the thigh in extension, and while still in the same posture the nurse puts a hand on the buttocks and pulls the thigh back, or sets a knee on the buttock and gently pulls the leg up from the bed, so as to stretch the quadriceps. The anterior thigh muscles may also be stretched by putting the patient on her back half off of the bed with a pillow under the pelvis, and by pushing the leg downward. The lateral motions to stretch the adductors are managed best by two nurses, but it is easy to effect them by sitting on the bed or lounge between the limbs, and so with both hands forcing the leg into abduction, while the other leg is stayed by the body of the nurse. The stretching of the posterior muscles of the thigh is also easily done by lifting the whole limb while the leg is in extension on the thigh. All motions should be firm and slow, so as not to arouse resistance, and as time goes on, should be repeated more often, as the distress lessens. At first the pain is annoying, but as I never propose so to stretch as to elongate the nerves extremely, it need not be such as to forbid progress. Nearly all old cases have a certain brawn-like hardness of muscle, and no doubt one does in all cases stretch and disturb somewhat the small nerves imbedded in these firm and unrelaxing tissues; but this is very different from the violent and painful nerve stretching above alluded to.

Whatever it is that we do by this process, if it be regular, steadily used, and done with thought-guided skill, it is assuredly helpful, and while it does not cure it brings in the end remarkable changes.

The hardness of the muscles lessens, the tissues get softer and sweat better, are less dry, the gait improves, the limbs get warmer, and, what surprises one, the general condition is often ameliorated. When you have reached a limit, and after some weeks, the favorable changes cease, it is time to see what more can be done by tendon sections which, at this stage, I am willing to use freely. After the wounds heal, indeed, pretty early, I return for a few weeks to the extensions, and train the

patient to imitate them, which, with the least ingenuity, is easy enough.

In many of the spastic palsies of childhood which follow a series of convulsions, or are due to some intracranial trouble of uterine life, you will find that some muscles are spastic, some less so, some contracted and inert. According to their condition and electrical and other reactions, are they to be dealt with. Some need extension, some want to be electrically stimulated, and need also massage. Each muscle and group must be considered, and the wants provided for. It is troublesome. It needs patience. It exacts intelligence—but it wins in the end. It is easy to cut off a prepuce or to put on a brace. But a brace is a prison, and I think a good deal before I condemn a muscle to its confinement.

I show you here a valuable group of cases. One, a man with an obscure spinal malady, probably sclerosis, has been at a stand-still for years. I failed to help him once, now I am trying again with new lights, and he insists that his gain is great. This case is hard to handle, because he is heavy, and the muscles strong. I cannot largely aid him. The second case was here years ago. I dismissed it in disgust, having simply done no good. Readmitted at my desire, she is here to illustrate a half year's result.

The patient, a girl of seventeen years, walks now before you. Observe the body rocking on the too rigidly held pelvis, the legs bending with effort, the jerk of the body as the foot falls, and the spasm of the gastrocnemius which refuses to let down the heel, so that she swings along, rocking on the ball of the foot. This symptom, which is so characteristic, is worth a moment's study.

If you put this girl on her back the limbs will still be spastic, but not as they are when she puts weight on the sole, the pressure at once increases the tendency to spasm. It is a reinforcing sensation, and radiates to the cord impressions which, as they reach the ganglia concerned, add to their abnormal excitability. It is no wild conjecture that this represents in excess a normal phenomena, and that in health pressure on the sole sends reinforcing energy into the ganglia, by aid of which we stand and walk. Years ago I failed with this case, which originated in prenatal troubles of which we know but little. A few weeks here of late have lifted her in health, abated her nervousness, increased her weight, and put her in a state to do manual work, despite the tremor you observe, and the persistence, in lessened degrees, of all her previous conditions. There is gain, not cure. Of late I have given her cod-liver oil, and now shall cut the tendon of the left gastrocnemius. The other heel comes well down at present, as it did not do a month ago.

I show you here a nice lad, æt. fourteen. Born at seven months, he held up his head at the end of a year. At his fourth year he could walk with difficulty —seizing at objects and often falling. This is a typical case of spastic disease from some obscure intrauterine disorder. When he came to me he was as now—clever and intelligent—but he fell about, could walk but a little without great fatigue. His thighs on violent adduction chafed one another, and he rose on his toes and pitched about in his walk. With his eyes shut he fell at once, and at no time was his equilibrium preserved save at the cost of great effort. The thigh adductors were stiff and hard, and the gastrocnemii were also abnormally firm. He had been braced by many doctors and then sent off to improve as he might. Of course, he has been circumcised. It did not do the least good. I have rarely seen a less promising case.

January 1, we began extensions and in the hands of a practised and thoughtful masseur, Mr. Penington, he showed good results in a fortnight. As he gained he was trained to stand with shut eyes, which did good. After two and a half months of persistent extensions he ceased to gain rapidly, and now I was able to know what tendons to cut. Dr. Wm. Keen divided for me the semitendinosus and semimembranosus on both sides, also the adductors of both thighs just below their origins.

In a few days later we resumed the extensions, and once more there was a new increment of gain. He still walks with his legs slightly flexed, and still stoops over his pelvis, but he can straighten both the legs and the trunk, and being interested and a lad of character will, by and by, and continuously gain in power and position. His temper has improved, his tendency to emotional expression passed away, and he has now ability to walk for two or three miles without aid of any kind. I never see him without a sense of pleasure at the gains thus acquired for an interesting lad.

I neglected to say that he had some distinct quantitative loss of faradic electric response in the lumbar muscles, and the flexors of the feet. These were treated by electricity and with positive improvements, which were aided by massage used only for the muscular groups in question.

I have said elsewhere that cases of spastic trouble in women are apt to wear the mask of hysteria, and to be excessively puzzling. I have seen a curious illustration of this but lately, and am glad here to relate this instructive case.

In the early winter, Dr. Sutton, of Pittsburg, Pa., confided to my care Miss C. L., of K. city, æt. twenty-nine. At twelve she had typhoid fever, and pneumonia thirteen years ago. From 1879 to August, 1883, she had asthma frequently, but it left her abruptly, and she had unusual good health until February, 1884. She was then attacked in the night, without known cause, by severe pain in the sacral and lumbar regions. This came and went up to August, 1886. It was at times absent—at times severe—a sense of weight, quite often unendurable. The pain had no relation to menstruation, which was regular and free from discomfort. During the year which followed she had less and less pain, but more and more difficulty of movement in rising and walking, and at times numbness in the hands and feet—which was, however, a transient symptom until early in December, 1886, when suddenly she became aware of abrupt loss of sensation in the right leg to the knee. About this time she began to feel a decided and constant sense of constriction around the abdomen, and to exhibit a more and more awkward gait.

February 8, 1887, I examined the case with these results:

The thoracic and abdominal viscera healthy. The secretions normal. Defecation natural. Slight difficulty in micturition. Menstruation regular and free from grave troubles.

Her mind was clear, her memory good, and her emotions under control, not a trace of hysterical tendencies, in fact, a well-balanced person. She was free or nearly free from the girdle symptom, but at times it was distinctly and disagreeably felt. Otherwise she had no pain and for months no sacral pain. To my surprise and hers, I discovered that she had entire analgesia with the exception of a region such as would be left uncovered by a ball dress rather low in the neck. Thus the normally sensitive territory dipped between the breasts and left them analgesic, crossed the shoulders and descended the spine in a narrow strip to the sixth dorsal vertebra. The boundaries were sharp and did not change, so that the neck, shoulders, and head were perfectly possessed of all forms of feeling. Below these, as I have said, there was no sense of pain. Pins could be buried in the flesh. Violent faradization of nipple or nail regions caused no annoyance. Cold was felt as heat in the legs, heat was not felt or dimly felt as heat, except in the soles, where high temperatures were known to be heat. Touch was everywhere indistinct, the toes were not distinguished correctly, and touch was usually referred to a point nearer the centre.

No pin-prick bled within the analgesic spaces even if the pin were of very large size. Vision was normal, the color field healthy. The plantar reflex persisted. The faradic and galvanic reactions seemed to be distinctly below the normal standard, and the responses came tardily, but, of course, comparisons were difficult as both sides were affected.

Her gait was curious and was like an extreme exaggeration of the motion of a woman with unusual breadth of pelvis. There was also the spastic element, the toes struck the floor as she moved forward, and at each step she was lifted abruptly by the spastic action provoked in the gastrocnemius by the pressure of the sole on the ground. She could not rise unaided nor walk without help. With shut eyes she fell at once. The knee-jerks and muscle-jerks were extreme and easily and largely reinforced. Very marked ankle clonus existed on both sides with exaggerated muscle-jerks. The left arm and hand were weaker by one-half than the right, but the reverse obtained as to the power of the lower limbs.

The combination of a mild form of spastic paralysis with analgesia, the girdle symptom, the absence of sphincter troubles all contributed to make this case somewhat bewildering. My friend Prof. Horatio Wood saw it with me twice. It seemed to us probable that there had been some distinct organic disease in the lumbar region of the cord; as to its nature we could hardly do more than guess. It was our belief that to this had been superadded symptoms which we should usually describe with little hesitation as hysterical despite the utter absence of a hysterical history or temperament, and of emotional causative disturbances.

Of this lady I was happy enough to make a good cure. Under the use of the wire brush and secondary induction currents with powdered skin, the analgesia disappeared in a few weeks. It faded in irregular spaces and at last none was left. The spastic muscles were treated by extensions, and as the spasms lessened more and more general massage was used. Absolute rest was preserved for two months and then followed a graduated course of muscle training and of exercise with shut eyes. Long after she was up I insisted on crutches to enable her to save labor for the legs and to lessen weight on the soles. She now walks fairly well, has no clonus, no pain, and is free from analgesia and gaining in vigor every day.

ORIGINAL ARTICLES.

EVERGREEN FORESTS AS A THERAPEUTIC AGENT IN PULMONARY PHTHISIS.[1]

By ALFRED L. LOOMIS, M.D., LL.D.,
OF NEW YORK.

If one studies the literature of medical climatology, he will find very few well-established facts, or even plausible theories, which satisfactorily explain the beneficial effects of change of climate upon pathological processes. Even the climatic treatment of phthisis, upon which the most careful attention has probably been bestowed, must still be regarded as unsettled.

We are unable as yet to formulate any exact statements as to the influence of even the more potent elements of climate, such as light, heat, and moisture, while our knowledge of the more obscure and imponderable factors is still more uncertain and chaotic.

Even the nomenclature employed by medical writers is inexact and confusing; the terms cold and warm, severe and mild, moist and dry may each individually find exact expression in figures, but one very soon becomes convinced from his clinical experience that their various combinations can be described in no such definite terms, and that purely meteorological factors are, in themselves, of little value in elucidating the subject, or in leading to safe conclusions.

Neither the density of the atmosphere, the amount of moisture, the equability of the temperature, the barometric oscillations, nor the amount of sunlight, are sufficient data from which to deduce the climatic influence of any locality; for clinical observations have established the fact that places having similar climates, so far as can be determined by their topography and meteorological conditions, have very different therapeutic effects.

As previous investigations have given us full and exact knowledge of the physical elements of climate, the necessary inference from a clinical standpoint was, that there are other unknown agents which either by their presence or absence determine in a large degree the results obtained in different climates. Modern pathology has given definite form to this clinical deduction.

The revelations of the microscope in the field of bacteriology, have made clear many obscure points, and given a strictly scientific basis to much empirical practice, especially in the treatment of pulmonary phthisis.

All recent writers on climatology seem to agree that the chief factor, and the one common to all localities that furnish favorable results in pulmonary phthisis, is purity of atmosphere. Formerly this

[1] Read before the American Climatological Association.

term applied almost entirely to purity of physical composition, but more recently, and in the light of advanced pathological investigations, it has come to imply freedom from those floating particles derived from inorganic as well as organic sources, which appear to the naked eye as motes in the sunbeam.

In air which has been rendered impure by the crowding together of human beings, these germs are found in such quantities as to be sensible to both smell and taste, although a large portion are so minute as to be beyond the power of the microscope, and can be detected only by solar rays. Dr. David Young, in his book on the *Tuscan Hills*, says: "Many of these minute organisms are now well known; and, besides playing a very important part in the causation of disease, they likewise fulfil many functions, not only invaluable but necessary to life. They are the essential agents in the digestion of our food, they make our bread, and turn our grapes into wine, without them our crops would not grow, and much of our dairy produce would be valueless. This teeming world of microscopic life thus contains innumerable agents of minutest form, highly serviceable to man, and many which are equally hurtful, and even fatal to him. Could we discover the means of destroying the latter, mildew and blight would disappear, and many infectious diseases would be unknown."

That there is some intimate connection between the development of the microörganisms of disease and atmospheric impurities, every day's clinical experience seems conclusively to establish. Dr. Angus Smith, in his work on *Air and Rain*, states that we have in the air organized living things which are capable of planting colonies wherever they can find food. These spores may be divided into many classes, the useful and the deleterious, those which promote health, and those which bring disease. The idea of any of them bringing health is not founded on anything positive, but we can scarcely imagine these numberless forms to be all useless. The idea that they bring disease is well confirmed, and ought to be the study of the medical professsion.

All varieties of putrefactive bacteria may have an atmospheric origin, and it is reasonable to suppose that the so-called specific bacilli may have a similar origin. It is to be remembered, however, that I am not now discussing whether the cause of disease be an organic substance formed in the process of decomposition, or an organic germ. But the tendency of inquiry in modern times has been to establish the belief that decomposing substances, both animal and vegetable, produce disease, and are intimately connected with infection and the production of those contagious germs whose absence renders any atmosphere pure or aseptic; such an air must act negatively, rather than positively, if its therapeutic condition be simply that of freedom from septic elements.

Considering, however, the rapidity with which all septic germs multiply, the innumerable sources of their supply, and the freedom and ease with which they are disseminated over large areas, it seems almost necessary to suppose the presence in aseptic atmospheres of some antiseptic agent. Extreme cold and high altitudes render air aseptic without the presence of any material antiseptic element, but the degree of the one and the extent of the other necessary to produce asepsis are such as to preclude their general employment in the treatment of septic diseases; moreover, clinical experience has shown that such an aseptic air has a less powerful curative effect upon ulcerative and suppurative processes than one in which the aseptic condition is due to the persistent presence of some antiseptic agent of sufficient power to destroy existing septic germs.

The air of high altitudes is aseptic; that of the sea is antiseptic by reason of the bromine and iodine which it contains. Since then the clinical fact is well established that phthisical processes go on far more rapidly in an impure or germ-laden atmosphere, the question is constantly coming to us, Where can we find an atmosphere that is aseptic because it is antiseptic, into which we can send our patients who are suffering from tubercular disease?

Having long since been convinced by my observations that evergreen forests have a powerful purifying effect upon the surrounding atmosphere, and that it is rendered antiseptic by the chemical combinations which are constantly going on in them, I invite attention to some conditions existing in such forests, which may explain their therapeutic power.

The belief that the atmosphere of evergreen forests has a curative effect upon persons suffering from pulmonary phthisis is a very old one. Dr. Walsh, in his works on *Diseases of the Chest*, states that the old Romans sent patients with ulcerated lungs to Libra, where, by breathing the balsamic effluvia of the pines, with which the country abounded, they were said to have lived many years freed from their complaints.

The atmosphere of pine forests has always been regarded as most favorable to consumptives by the non-professional public, and there is usually some good ground for a widespread and long-standing non-professional belief in the therapeutic efficacy of any locality. Various attempts have been made to explain the beneficial effect of these forests, some have attributed it to the sedative influence of the terebinthinate vapor constantly floating in the air of such localities, which, by its action on mucous surfaces, arrests diseased processes; others have attributed it to the deoxygenation of the air by the terebinthinal vapors; others to the action of resinous aromata; and still others, to some change in the electrical condition of the atmosphere, the result of the friction of the air against the sharp needles of the evergreen trees.

Such ambiguous terms as "balsamic influence," "health-giving emanations," and "aromatized atmosphere," must be regarded as empty phrases, and meaningless as scientific explanations. The clinical evidence, however, of the beneficial effects of pine forests on phthisical subjects is unquestionable, and it has been accepted by most careful clinical observers that they are an important adjunct in the treatment of phthisis.

The changes attributable to the persistent inhalation of air impregnated with the emanations of such forests are such as to indicate that the atmosphere is not only aseptic, but antiseptic, made antiseptic by

some element which is not alone fatal to germ life, but at the same time is stimulant and tonic to normal physiological processes within the lung. Such an antiseptic the chemical laboratory has thus far failed to supply; but as we weigh carefully the facts presented to us in the study of this subject, we are led to the conclusion that this antiseptic element of evergreen forests, an element which is not found elsewhere, is the product of the atmospheric oxidization of turpentine.

It is well known that the turpentines alone have been regarded as of special service in the treatment of all forms of catarrh, especially catarrh of the respiratory surfaces. Atomized solutions and vapors of turpentine have been employed by inhalation in all forms of disease of the respiratory organs, and its internal use has long been regarded as a most valuable remedial agent in the treatment of infectious diseases. Its use in all these different ways has been, to a certain extent, empirical. Dr. Ringer, in his *Handbook of Therapeutics*, states, in addition to its other effects, that turpentine acts antiseptically, passes readily into the blood, and may be detected in the breath and perspiration, and in an altered state appears in the urine, giving it an odor of violets or mignonette.

Recently terpine, an active principle of turpentine, has been employed in antiseptic surgery, and has proven a most powerful deodorizer and antiseptic, both within and without the body. From these and many other similar facts which might be quoted, it would seem evident that the local and constitutional effects of turpentine are those of a powerful germicide as well as stimulant. Its presence in the atmosphere of pine forests cannot be questioned. Again, ozone is said to be present in excess in the air of evergreen forests, and the beneficial effects of such an air have been ascribed to this substance alone. Soret states that when ozone is brought into contact with turpentine, the whole molecule of ozone is absorbed and no oxygen remains, so that it seems evident that there is a close relation between an excess of ozone in the atmosphere and turpentine exhalation.

Recently the disinfectant property of peroxide of hydrogen has been attracting attention, and it has been shown that it is either fatal to certain forms of germ life or that it renders them inoperative, so that putrefaction processes are arrested or prevented. The oxidizing and antiseptic power of the peroxide of hydrogen have been proven by numerous experiments, among which may be mentioned those of P. Regnard (*Gazette Médical*, 1880).

The researches of Saböni, made near Moscow, published in the *Bericht Deutsch. Chem. Gesel.*, vol. viii., and abstracted in Petterkofer and Ziemssen's *Handbuch*, have proved beyond question that peroxide of hydrogren is almost certainly present in varying amounts in the air and rain, and less frequently in snow and hail, and that the amount varies with the season, with the wind, the amount of moisture and in different kinds of forests, the larger amount being found among pines. It has also been demonstrated that all kinds of aromatic plants produce it, and that many natural processes give rise to it which have been regarded as exclusive sources of ozone. As its tests are similar to those for ozone, it has doubtless been mistaken for it, as experiment shows that if turpentine is heated in contact with a stream of air, peroxide of hydrogen is produced.

Mr. Kingsett states that it is probable that each molecule of the oil of turpentine gives rise, in the process of oxidation, to a molecule of the peroxide of hydrogen, and that when turpentine is exposed to the action of the atmosphere it absorbs oxygen and evolves a peculiar organic oxide, which remains dissolved in the turpentine, communicating to the surrounding atmosphere properties similar to those of the peroxide of hydrogen; also that by natural atmospheric oxidation of the terebinthinates, there is produced in extensive pine forests an almost illimitable amount of peroxide of hydrogen, which renders the atmosphere of such forests antiseptic.

The supposition that peroxide of hydrogen exists in excess in the air of any locality is thus based upon the presence in the air of such localities of the vapor of the oil of turpentine or of other allied substances. It has been shown by Schönbein and others that peroxide of hydrogen may be produced in large quantities by the combined action of air, light, and moisture upon ether, alcohol, oil of turpentine, and other essential oils, and it has been further shown that ozonized turpentine itself contains, not ozone, but peroxide of hydrogen. It seems evident, therefore, that an atmosphere containing the vapor of turpentine or allied substances would be richer in peroxide of hydrogen than that of other situations.

Since putrefactive processes within the pulmonary tissue, no less than in any other situation, are due to, or accompanied by, the presence of various forms of bacteria, the continual bathing of the ulcerated surfaces with such a powerful antiseptic as peroxide of hydrogen, cannot have other than a decided effect in arresting the formation of the products of decomposition. Dr. Clifton Allbutt says (*Lancet*, June, 1878): "For many years I have held that the majority of phthisical patients die of septicæmia, and that the arrest of this daily repoisoning is a primary object of treatment. To wash, cleanse, and dress ulcers of the lungs by surgical methods is impossible; if, however, there be an aseptic or antiseptic climate, we may hope to counteract this secondary blood poisoning, by sending our patients to live in it. If then an antiseptic atmosphere, although not fatal to the tubercle bacilli, will destroy the products of germ life of septicæmia and pyæmia, it will accomplish much in the arrest of phthisical processes.

The more recent developments in the (Bergeon) treatment of phthisis by gaseous injections, if they shall be found beneficial, are apparently due to the arrest of septic poisoning, and not to destruction of the tubercle bacilli. It is my belief that the atmosphere of evergreen forests acts in a similar manner, and the facts which I have brought before you from many sources, seem to prove that the antiseptic agent which so successfully arrests putrefactive processes and septic poisoning, is the peroxide of hydrogen, formed by the atmospheric oxidation of turpentine vapors.

The crucial test of medicine is not in the cure, but in the prevention of disease, and I fear that the terrible death-rate from pulmonary phthisis, which has so long defied the advances of medicine, will never be greatly reduced, so long as we confine ourselves to its cure, or attempt to destroy specific bacilli lodged in some endothelial cell or lymphatic capillary. These are the impregnable citadels of germ life. If we hope to destroy them or render them inoperative in phthisical processes, it must be done through the respired air.

It is not possible for every one to take his weak lungs to an aseptic air, but it is possible to render the air of most localities antiseptic; I therefore would impress not only the profession but the public, with the importance of preserving our evergreen forests, and of cultivating about our homes, so far as possible, evergreen trees.

Dr. Dobell states that wherever the pine, with its constant exhalation of turpentine vapor, and its never-failing foliage, can be distributed in a proper proportion to the population among the houses of men, the atmosphere can be kept not only aseptic but antiseptic by nature's own processes, independent of other influences than a certain amount of sunshine and moisture—elements which, like the pine itself, can be found wherever human beings can form a home.

EPISTAXIS.[1]

BY E. FLETCHER INGALS, A.M., M.D.,
PROFESSOR OF LARYNGOLOGY, RUSH MEDICAL COLLEGE; PROFESSOR OF DISEASES OF THE THROAT AND CHEST, WOMAN'S MEDICAL COLLEGE, CHICAGO.

I MAKE no apology for writing on a subject as old as man, for I have learned by experience that the busy physician is much less interested in what is unique than in that which is liable to occur at any time among his own patients. However, I will have but little to say of the forms of this affection with which all are familiar, but will report cases sufficiently rare to be of interest, yet withal so grave as to merit the most careful consideration.

Epistaxis has been treated of by medical writers since the earliest ages, but something of interest may still be said of it; for within our memory great advancement has been made in the means of accurate diagnosis, and corresponding improvements have come in vogue in the methods of treatment. At this time we need hardly consider the simple bleeding from the nose which occurs in nearly every child, with or without provocation, and which ceases spontaneously, like ordinary bleeding from the lungs, and is consequently readily cured by any of the mystic rites so well known by the public.

Epistaxis is occasionally met with, that, either on account of its frequent recurrence, or the large amount of blood lost, becomes a source of great inconvenience, or of actual danger to the patient. In young people the most common cause of epistaxis is picking scales of dried mucus from the nares. In old people degenerative change in the bloodvessels is a frequent cause, and during middle life excitement, direct injuries or strains, or vigorous blowing of the nose, acting upon an ulcerated or eroded mucous membrane, are the most frequent causes. Among the common, but less frequent causes, are changes in the constitution of the blood itself, obstruction to the circulation through the kidneys, liver, lungs, or other organs; and malignant or fibrous tumors of the nares or naso-pharynx. Inhalations of irritating dusts or vapors, and many other trivial accidents, are among the less important factors in causing the affection. In children or young adults the bleeding is often a safeguard which prevents the evil effects of plethora, and in women the hemorrhage may be but vicarious menstruation.

The hemorrhage which occurs in scurvy and low forms of fever is usually due to changes in the constitution of the blood, as is also that resulting from the hemorrhagic diathesis. Sometimes there exist not only changes in the blood itself, but also in the mucous membrane; as, for example, in diphtheria. Several other infrequent causes might be named, but these are sufficient.

In plethoric persons, and often in those suffering from the low forms of fever, epistaxis is preceded by a feeling of fulness of the head, flushing of the face, giddiness, tinnitus, and itching of the nose, which symptoms are relieved by the bleeding. In the majority of cases the blood flows from one nostril drop by drop, the amount lost with one attack seldom being more than half an ounce or an ounce, and then the bleeding stops spontaneously. But in serious cases the blood may flow in a stream, and in cases dependent upon blood changes it often comes from both nostrils. In these cases the amount of blood lost will vary from one to many ounces. Some patients have been known to lose several pints in two or three days.

As a result of frequent or severe hemorrhages the patients become weak and anæmic, and suffer from neuralgia, giddiness, and other symptoms of cerebral anæmia. In the more severe cases dangerous, or even fatal syncope, may occur; but when we consider the amount of blood that is frequently lost by these patients it is a matter of surprise that a fatal termination is not more frequent. However, before the introduction of the method of plugging the posterior nares for checking epistaxis deaths from this cause were not very uncommon. In old people bleeding of the nose from slight causes is a grave symptom, indicating degenerative changes in the bloodvessels, which, sooner or later, are liable to terminate in apoplexy.

In all annoying or dangerous cases a critical rhinoscopic examination should be made of the nares and naso-pharynx, in order to discover any local cause for the hemorrhage, such as erosions, ulcers, or morbid growths. Nearly always the physician will be rewarded for his pains by finding the source of the bleeding. The appropriate treatment for epistaxis is of two kinds, viz., that designed to check the hemorrhage at once, and that to prevent its recurrence. Usually, when epistaxis occurs in the plethoric, when it is a vicarious discharge, or when it is due to venous obstruction, as not infrequently happens in hepatic, pulmonary, or cardiac disease,

[1] Read before the Illinois State Medical Society, May 19, 1887.

the physician should not try to check the bleeding unless serious symptoms supervene. But when the face becomes pale, and the extremities cold, when faintness occurs, and in all cases due to an abnormal condition of the nasal chambers, prompt measures should be adopted to prevent loss of blood. For this purpose, compressing the nostrils and holding them ten or fifteen minutes, until a firm coagulum has formed, is one of the most simple and efficacious methods. The application of cold to the brow, the nape of the neck, or even to the feet or hands, may be equally effective; or very hot water may be applied freely to the nose and face with like result. Sometimes the bleeding spot may be reached by the finger passed into the nostril and then direct pressure should be made upon it.

Having syringed out the nose with cold water, the insufflation of powdered matico leaves, alum, or tannin will often speedily give relief. Astringent sprays may be used for the same purpose, though they are less satisfactory than powders. The insufflation of a four per cent. powder of cocaine with sugar of milk will sometimes act promptly and agreeably. The iron styptics are most commonly employed, but they are far more disagreeable, and I believe much less effective than tannin.

One of the best means for checking bleeding by local remedies is—first, syringe out the nose with cold water, and then insufflate a powder containing a small amount of cocaine, which should be followed at once with powdered tannin. As the clot to be formed in this way must remain for several hours, it is a good plan to use iodoform with one of the other powders. After the powder has been applied the nostrils should be compressed, or they may be plugged with lint or cotton until bleeding ceases. This treatment will be effective in most cases, and it has the further merit of being less disagreeable to the patient than most other methods. However, it may fail, and then more thorough anterior or anterior and posterior plugging must be employed. This latter method is effective, but is exceedingly uncomfortable to the patient, and if the plug has to remain for many hours in the naso-pharynx, it is liable to set up inflammation of the Eustachian tube or middle ear. I have known of one case in which it caused dangerous inflammation of the mastoid cells. The late Professor Gross was authority for the statement that patients have frequently died from the effects of septicæmia caused by the post-nasal tampon. Other physicians have reported as resulting from it erysipelas, tetanus, gangrene, etc. If posterior plugging becomes necessary, it may most easily be effected with the aid of a soft catheter through which a double thread has been passed previous to its introduction into the nostril.

I adopt a method of plugging the nares which has proven most satisfactory, and which, I believe, may be made effective in all cases where the bleeding is not from the naso-pharynx. I take a piece of surgeon's gauze, or cheese cloth, an inch in width, and four or five feet in length. This is thoroughly saturated with tannin, which is prepared by rubbing it up with just sufficient water to make a thin, syrupy mixture. Opening the nostril with a nasal speculum, one end of the slip is folded upon itself, and over the end of a probe, by which it is carried quickly to the posterior part of the nasal cavity—a distance, in the adult, of about three and one-half inches; after this fold after fold is carried back in the same manner, though more slowly, until the cavity is completely filled, when any remaining portion of the slip is cut off. It is necessary to carry in the first fold quickly, otherwise the coagulating blood causes it to adhere to the sides of the nasal cavities and renders the subsequent filling of the back parts very difficult. If iodoform has first been blown into the nasal cavity, or has been freely mixed with the tannin, in which the gauze has been saturated, this plug may remain for two or three days without danger. When the time comes for its removal, the patient catches the end at the nostril, and pulls it out slowly and gently.

There is some liability of crowding in a part of the gauze so far that it would hang down behind the palate, but this can be easily avoided by care when the source of hemorrhage is not far back; and it may then be avoided by tying to the end of the gauze which is first introduced a number of silk threads, one every two inches, which are allowed to hang from the nostril until the naris is completely filled. These threads are then pulled firmly enough to pack the gauze thoroughly at the back part of the nasal cavity.

Whenever the tampon is used in the posterior nares a string at least two inches in length should be left hanging from it in the pharyngeal cavity to facilitate its removal. It should not be left in position more than thirty-six hours, if avoidable, and the nares should be carefully cleaned and disinfected after its removal.

The constitutional remedies for checking hemorrhage, or preventing its recurrence, such as acetate of lead, ergot, gallic acid, sulphuric acid, and turpentine, may be employed in mild cases, and should have a trial in those of greater severity, when the exact point of bleeding cannot be ascertained. The bleeding due to plethora is best prevented by occasional saline cathartics.

In the great majority of cases of obstinate or frequent epistaxis a careful examination of the nares, under a strong light, will reveal the spot from which the blood escapes. When this can be detected, the best method of treating is to cauterize the spot with either solid nitrate of silver or the galvanocautery; the latter is most satisfactory, but the former will often answer the purpose. During a few months past several cases of serious epistaxis have came under my observation, brief reports of which I am confident will be of interest to you.

Case I.—A. D. P., æt. about forty-five, mechanic. The patient had been suffering from frequent epistaxis for about four months, the bleeding coming on three or four times every day, and from half an ounce to two ounces of blood being lost each time. As a result he was greatly debilitated, and unable to attend to his business. Examining the right naris, from which the hemorrhage occurred, I found the mucous membrane covered with blood, but even after cleansing it I was unable to see the

bleeding point; however, I found that the blood came from the anterior portion of the external wall above the inferior turbinated body. This region I cauterized with a flat electrode, shielded on the opposite side. Two or three treatments were necessary before I succeeded in overcoming the difficulty, but then the patient was completely cured.

CASE II.—A. H. H., æt. nineteen, cashier. For a year had been troubled with bleeding from the nose three or four times a day, losing from one to four drachms each time. As a result he had lost considerably in weight, was weak, short of breath, anæmic, and suffered frequently from headache. He continued at his business, but found the epistaxis exceedingly annoying and debilitating. His tongue was coated, appetite poor, and digestion imperfect. He had received the ordinary constitutional remedies, but without apparent benefit.

Upon a rhinoscopic examination, I found the walls of the left naris covered with blood; but by wiping it away, I discovered a small polypus near the middle of the middle meatus, and near it a small, bleeding papillary body. Having anæsthetized the part, I cauterized the polypus and bleeding-point. Five days later the bleeding had not entirely ceased. I again cauterized the spot from which the blood escaped. This completed the cure, and there has been no return of the hemorrhage.

CASE III.—G. W., æt. thirty-three, liquor-dealer, had been troubled with profuse and frequent epistaxis for ten years, but for a couple of weeks previous to seeing me the hemorrhage had occurred about every second day. In this case the blood would sometimes spurt in a stream, two or three feet from the nostril, and would often continue to flow until faintness occurred. The patient was quite anæmic and weak at the time, but otherwise seemed in good general health, and complained only of headache whenever there was a long interval between the hemorrhages. I found, also, that previous to the occurrence of epistaxis he had suffered from hemorrhoids.

In this case it seemed that formerly the hemorrhages had been beneficial by relieving plethora, but latterly they were affecting the patient seriously because of their frequent occurrence. He stated that he usually lost from one to four pints at each hemorrhage.

Upon examining the nares, I found a small, eroded surface in the left side, on the cartilaginous septum, partially covered with a scale of clotted blood. The right side appeared slightly eroded, but did not show signs of bleeding. I touched the eroded surface on the left side with a galvano-cautery electrode heated to redness, but immediately blood spurted from an artery as large as a knitting-needle, and could not be checked by the hot wire. The patient lost half a pint within five minutes, and the flow was only checked then by plugging the nostril with gauze saturated with tannin, as recommended above. Two days later I removed the plug, and there was no bleeding, but blood had been flowing from the right side of the cartilaginous septum, at a point nearly opposite that from which bleeding had occurred on the left side. When my assistant tried to anæsthetize this side preparatory to cauterization, the slightest touch started the blood. Finally, I touched the bleeding points slightly with the hot wire, but immediately the blood spurted from two small arteries. I then made deep cauterizations and finally checked the hemorrhage, except slight oozing, which was stopped by the tannin tampon. The time occupied in the cauterizations was not much over five minutes, but the patient lost a pint of blood. A few days later he returned, having had bleeding again from the left side. The moment the mucous membrane was touched, blood ran in a stream, so that half a pint was lost within five minutes. The bleeding points were cauterized again, and the hemorrhage checked. I did not see the patient again, but I have heard that he is still troubled with epistaxis.

In this case the treatment was unsatisfactory, every application of the cautery being attended by profuse hemorrhage. I have no doubt that the bleeding could have been checked from these particular spots if he had continued treatment, and by a judicious use of cathartics the plethora might have been otherwise relieved; but I am not surprised that the patient became discouraged.

CASE IV.—Mrs. H., æt. about thirty, had been annoyed by epistaxis three or four times a day for four weeks, which to her had become alarming, though the amount of blood lost had not been sufficient to affect her general health. An examination of the nares with a strong light revealed a bleeding point on the left side of the cartilaginous septum. The mucous membrane was anæsthetized with cocaine, and the point cauterized, with the result of effecting a permanent cure.

CASE V.—The notes of the following case were kindly furnished me by my friend, Dr. J. E. Rhodes, of this city. "R. J., æt. seventy-three, in fairly good health, was seized with epistaxis in the middle of the night, while resting quietly, the blood-stream being continuous, and about the size of a knitting-needle. After a considerable loss of blood, the flow was stopped by cold water applied to the back of the neck. The hemorrhage was controlled in like manner twice subsequently, but the third time the loss of blood was so great that a neighboring physician was called in, other means were resorted to, and plugging of the posterior nares became necessary before the hemorrhage could be stopped. I was summoned, and on my arrival found the patient much exhausted from loss of blood (estimated at about two quarts at this time), and the friends in alarm because efforts had hitherto afforded temporary, but promised no permanent relief. There was no bleeding at this time, but during the next few days there were several hemorrhages, each time controlled by gauze saturated with a mixture of tannic acid, as recommended by Dr. Ingals. This measure would stop the flow, but a few hours after removing the plug bleeding would return. Finally, a thorough examination was made, and the exact bleeding spot located. No galvano-cautery was at hand; therefore, at Dr. Ingals's suggestion, the spot was thoroughly cauterized with fused nitrate of silver. The epistaxis was completely and permanently controlled, much to the delight of the patient, whose suffering

from the posterior plugging had been intense, and who had become well nigh hopeless of permanent relief."

In conclusion, I wish to reiterate the following points:

1st. In ordinary cases, epistaxis ceases spontaneously; therefore, it makes no difference what innocuous treatment is employed.

2d. Epistaxis in children and young adults is generally an effort of nature to relieve plethora, and therefore should not receive active treatment.

3d. Persistent or frequently recurring bleeding from the nose may sometimes be relieved by constitutional remedies, but it usually demands topical treatment.

4th. When bleeding is profuse, it may often be checked by insufflations of cocaine, or the vegetable astringents, which may, if necessary, be supplemented by plugging the nostrils.

5th. When it cannot be checked in this way, the nasal cavity should be treated with iodoform, and then thoroughly plugged from the front with a strip of gauze saturated with tannic acid. This method will nearly always be successful, and, therefore, tamponing of the posterior nares, which is sometimes dangerous, should be employed only as a *dernier ressort*.

6th. In nearly all cases the source of hemorrhage may be detected by careful rhinoscopy.

7th. In these same cases the affection may generally be cured by the judicious use of solid nitrate of silver, or, better yet, by the galvano-cautery.

64 STATE STREET, CHICAGO.

THE RECTAL TREATMENT OF PHTHISIS.

BY H. A. MACCALLUM, M.D.,
OF LONDON, ONTARIO

ON February 2d I first began this treatment, and from ignorance of Bergeon's details fell upon a method of administering this remedy which, as may be seen, is wholly unlike his. Instead of using the remedy in the gaseous state, I inject the watery solution into the bowel, depending on the mechanical and physiological action of its mucous membrane to free and absorb the gas. A perfectly saturated solution is prepared (not less than eight hours should be taken for saturating cold water with sulphuretted hydrogen gas), of which ʒviij are diluted with ʒxx–xxx of water, and securely corked in ale-bottles. The contents of one of these, night and morning, after warming to 90°, are slowly injected into the bowel; not less than thirty minutes should be taken to do this. It is necessary to observe such precautions as would be taken in rectal alimentation, viz., the exclusion of air, the compression of the sphincter ani with the fingers, and afterward by directing the patient to extend the lower limbs. With some patients I precede the solution with laudanum. The majority, after gaining skill and confidence, retain the solution altogether.

As to results: The profession will be disappointed if they look for a "positive cure from phthisis" in this remedy. In no single case have I used it alone, and any results that were extremely favorable might not be wholly ascribable to the rectal mode of treatment.

I would not be surprised to find that the mass of the profession, who are now giving, or about to give this drug a trial, will discard it as worthless, because they are looking for results I feel sure they can never obtain. I think I am fair when I say to patients who have troublsome pains in the chest, expectoration of vast quantities of muco-purulent matter, and but slight loss of flesh, that it is a remedy of great value. Its tendency to disorder digestion, however, greatly diminishes this.

From some crude experiments I am satisfied H_2S is an antiseptic, and to this action I attribute what virtue it possesses. One observer, Hoppe-Seyler, found that H_2S reduced oxyhæmoglobin to hæmoglobin, and after prolonged action a sulphur compound, probably hæmoglobin sulphide, was formed. This work was conducted on pure hæmoglobin. This peculiar action of H_2S on hæmoglobin may possibly occur in this mode of treatment in the blood of the intestinal vessels. If not in union with blood, like oxygen, this gas is carried in solution on its way from the bowel to the lungs.

I have seen three toxic cases. The symptoms of Miss A. will answer for all. She took ʒxij, properly diluted, in three minutes. Five minutes after she complained of oppressive breathing. Her face became pallid, and "her eyes turned up." She passed rapidly into a state of syncope, from which she revived by feeble efforts at vomiting, The solution was still in her bowel when I was called to see her. I ran it off with a hard rubber tube, and gave her brandy. One hour after I found her recovered with the exception of some gastric disturbance, pulse 108, temperature 97°. All three rapidly recovered; had subnormal temperature and gastric trouble for two days. Some patients bear ʒxx diluted without trouble, if more than thirty minutes be taken for its introduction.

I prefer the solution to the gas for the following reasons:

1. The dose is uniform. In Bergeon's method the dose depends on the temperature and strength of the solution.

2. There is no apparatus wanted except a household syringe. I generally prepare several bottles at a visit, directing them to be kept in a cool place. The nurse can prepare the bottles, and in this way patients at a distance can be easily treated.

3. The solution causes less pain to the patient (if it is rejected, another bottle can be used).

4. There is no call for the use of carbon dioxide —a gas considered valueless, and contra-indicated. To say CO_2 is antiseptic is contrary to all physiological truths, and if it possesses any value in phthisis it is due to its sedative action. The blood appears to take up oxygen more rapidly after its use, but even this action is only temporary.

5. Bergeon failed with chlorine gas. I was able to give it in solution and found it well borne. I did not give it for any time, fearing it had a tendency to produce anæmia, by combining with the iron in the hæmoglobin.

In conclusion, I might say this remedy has no value in any but pulmonary lesions of tubercular phthisis. I made no examinations of the bacillus except for diagnosis, for I consider their disappearance from the sputa while the patient is under treatment as proof of the arrest of suppuration in the lungs, and nothing more.

A CLINICAL CONTRIBUTION TO DISEASES OF THE VITREOUS BODY.

By H. F. HANSELL, M.D.,

CHIEF CLINICAL ASSISTANT, EYE DEPARTMENT JEFFERSON MEDICAL COLLEGE HOSPITAL, OPHTHALMIC SURGEON TO THE SOUTHWESTERN HOSPITAL

In reviewing ophthalmological literature in search of material on the subject of diseases of the vitreous humor, one is surprised at its poverty. The study of microscopic normal and pathological anatomy is monopolized by Hænsell, of France, who in the past few years has contributed numerous and valuable additions to our knowledge ("Bull. Clin. Nat. Ophthal. de l' Hospice d. Quinze-Vingts"). The study of the clinical diseases seems to be limited to a superficial consideration of the different varieties of opacities as associated with diseases of the uveal tract, and with myopia; to an occasional report of so-called hyalitis, and, by our German brethren, of cysticercus.

The vitreous body consists anatomically of a transparent gelatinous material containing cells, interlaced with connective tissue, and surrounded by an elastic, homogeneous, and transparent membrane, the hyaloid. A few cells with one or more nuclei have been found attached to the inner surface of the hyaloid, and are described by Iwanoff and others as a part of the vitreous, and the source of its growth, and by others as white blood-cells which have wandered in from the vessels of the retina and ciliary region. The latter is probably the true belief, for the cells are too few in number and too irregularly placed to fulfil the duties of an epithelial layer. The vitreous is nourished by the surrounding vascular coat as the cornea is nourished by the loops of ciliary vessels at its periphery; and, like it, has no vessels in its own substance except in disease, when offshoots from ciliary vessels find their way into its tissue. In both cases described below, parallel, straight vessels could be plainly seen immediately behind the lens, but in the section examined under the microscope no trace of these vessels could be found.

Case I.—James A., aged three years, rachitic. Between Christmas, 1885, and New Year's, 1886, the boy had chickenpox. Before he had altogether recovered, the mother noticed a peculiar appearance of the left eye, and the boy complained of photophobia and lachrymation. On January 13th I found a pericorneal zone, which gave a light pink hue to the sclera, slight conjunctival injection, cornea clear, pupil fairly dilated and immovable, one small posterior synechia, lens clear, anterior chamber shallow, pupillary border of iris pushed forward. From the pupil shone a clear yellowish-white reflex, which came from a substance in the middle of the vitreous. T.—½. No pain or sensitiveness to pressure. No light perception. Ten days later the following condition was found: Cornea clear, anterior chamber annihilated, lens pushed forward and separated from the cornea only by the iris, and its site occupied by the yellow mass. The reflex came from immediately behind the lens, from its posterior pole to the ciliary region, as far as could be seen, occupying the entire vitreous chamber. The mass had become vascular, at least on its anterior surface, the vessels showing distinctly, running parallel to each other from the periphery to the axis. The external injection had not increased, nor had the symptoms become worse. January 24, the eye was enucleated. Healing normal.

Case II.—William, aged sixteen, who, while convalescent from typhoid fever, became blind in the left eye. No pain. Examination showed cornea clear, anterior chamber annihilated, pupil dilated and immovable, two posterior synechiæ, lens clear and dislocated forward, pressing against the cornea. Yellowish-white reflex from the vitreous. The vitreous body was filled with pus. Behind the lens and adjacent to it could be seen numerous straight parallel bloodvessels running from the ciliary region toward the axis of the ball. Without unnecessary delay the eye was enucleated. Healing favorable. The right eye had been in imminent danger. V.=$\frac{15}{CC}$ on first visit. Vitreous full of shreds. Here was a true hyalitis, with no ophthalmoscopic signs and no symptoms of inflammatory process either in the nerve or retina, choroid, or ciliary body, which, if convalescence had been delayed, or for any reason, local or general, the nutrition of the eye had continued without improvement, would have resulted in a purulent inflammation, with loss of the eye. The effect on the right of the enucleation of the left, if perceptible, could only have been favorable. Six weeks later an artificial eye was inserted into the left socket. The V. of right had improved to $\frac{15}{XL}$. It finally became $\frac{15}{XV}$.

The pathological appearances in both cases were similar; one description only is necessary. Bulbus hardened in Müller's fluid. Cornea and lens normal, but opaque from action of the fluid. Lens dislocated in its capsule forward, carrying the iris against the cornea, obliterating totally the anterior and posterior chambers. The vitreous body is compressed into a layer of about 1‴ in depth, and lies against the posterior surface of the lens and suspensory ligament. The retina is totally detached, and lies immediately back of the compressed vitreous, in a confused mass. A narrow red line, consisting of retinal bloodvessels and clotted blood, connects the retina with the nerve. The vitreous chamber, except that small part occupied by disorganized vitreous and retina, is filled with pus. The choroid is normal and in place. Sclera and nerve normal. The parallel "vessels" seen before enucleation behind the lens were retinal, or new branches from the ciliary, which is more probable, or no vessels at all, but extravasated blood from retinal arteries.

The microscope throws little further light on the condition. In the section examined no trace of new blood-vessels running from the ciliary body into the vitreous, or the pus which filled the vitreous chamber, could be detected. The vitreous substance was compressed or atrophied into an exceedingly thin membrane lying against the posterior surface of the lens, and into the angle formed by the suspensory ligament and ciliary muscle. Retina detached and floating in pus. Ciliary muscle and processes compressed, with no decided changes. Choroid normal. Pus cavity bounded by a thick membrane, which was lying in juxtaposition with the choroid.

The name suggested by Brailey, "spontaneous suppurative hyalitis" (*Trans. Oph. Soc. Unt. Kingd.*, vol. iii.), is appropriate for these cases. The term "hyalitis" is almost obsolete, being seldom met with in the works of recent writers, but if we understand inflammation of the vitreous chamber, and not inflammation of the hyaloid membrane alone, this term designates the nature and seat of the disease. The hyalitis of the old writers is the partial inflammation of the uveal tract—choroiditis or cyclitis with vitreous opacities of the present. While this is correct in many instances, there can be very little doubt that in the few a true inflammation of the vitreous body exists. Estlund (*Arch. f. Ophth.*, xv., 1869) found no trace of inflammation of the choroid in twenty-eight cases of purulent vitreous following typhus fever. He called the disease a cyclitis, because the vitreous was filled with white blood-cells and opacities. The vitreous derives its nourishment from the uveal tract, and any disturbance in the circulation through the vessels of the choroid will be followed by disturbance in the vitreous, which may be intense enough to result in its destruction through purulent inflammation; this is properly a spontaneous suppurative hyalitis.

The right—good—eye of Case II., where the only symptom was vitreous opacity, well illustrates the primary stages of the disease. There was no post. synechia, infiltration of the iris, loss of transparency of cornea or other sign of cyclitis—vitreous opacities excepted; nor could many careful examinations repeated when the vitreous had regained nearly its normal transparency prove the slightest trace of choroidal or retinal inflammation. The retention of the power of accommodation in this eye, and others that recovered (Logetschnikon, *Arch. f. Oph.*, vol. xvi.), is a more or less positive proof of the absence of any severe form of cyclitis.

In Case I. the patient came under observation before the entire vitreous was involved, and the gradual progression of the yellow reflex, until the mass had dislocated the lens into the anterior chamber, was watched. The pus must have formed in the posterior half of the vitreous chamber with little or no involvement even late in the disease of the ciliary region. The usual symptoms of cyclitis were wanting; there was no pain, no sensitiveness either to light or pressure, no want of transparency in the aqueous, or swelling of the iris, and no marked ciliary or conjunctival injection. Cases in which this yellow reflex has been the only peculiar sign of disease, have been mistaken for glioma of the retina, and the error being discovered after enucleation, have been described in a spirit of justification as "pseudo-glioma." This name would suggest a tumor of the retina, which, while not identical with glioma, might be similar to it. Hence it is misleading. Moreover, it expresses no intimation of the true character of the disease, its seat, or its pathology, and should be discarded.

The anatomical examination of the vitreous after the entrance of a foreign body, which has lighted up a circumscribed inflammation, teaches, as is evident from the experiments of Pagenstecher, that there is formed in the irritated part an abundant collection of cells, which show transition stages into connective tissue elements, into which, finally, a portion of the vitreous is transformed. Formerly, before diapedesis was recognized, when, after the entrance of a foreign body in its immediate neighborhood, numerous lymphoid cells were found, without the least change of the stroma cells of the choroid surrounding the wound, we believed ourselves justified in the conclusion that the tissue-cells of the vitreous were the source of the new-formed elements. Pagenstecher's experiments convinced him that the different varieties of cells found in an inflamed vitreous were lymphoid cells in transition stages. It is from these cases in which after a wound, rapid pustulation of the vitreous occurs before a choroiditis suppurativa could have been developed, that v. Gräfe and others have been led to separate the somewhat similar pictures of suppurative hyalitis and purulent choroiditis. "Here is the opportunity to convince one's self that a vitreous abscess can be developed before the slightest signs of inflammation show themselves at the wound." (Von Gräfe and Sämisch, Handb., vol. iv.) The choroid becomes affected only in the late stages, when phthisis is commencing. This long delay is explained by the protection afforded by the thick capsule which forms around the pus; the retraction and breaking up of this capsule, with the irritation it induces, causes irido-choroiditis.

Hutchinson (*Med. Times and Gaz.*, 1872, No. 151) describes a primary pustulation of the vitreous seen in eyes in which the cornea has long been destroyed through ulceration. The pus forms spontaneously with considerable œdema and swelling of the neighboring parts, with a detachment of the pus-infiltrated retina. The choroid retains its normal condition. Stelwag, in a comprehensive account of hyalitis in its different forms, traumatic, contiguous, or spontaneous, makes no mention of fevers as a cause. He describes, however, a purulent hyalitis which very rarely is caused by tuberculosis in which the whole vitreous becomes purulent and partly vascular, the vessels proceeding from the retinal vessels and running in every direction. Nettleship (*Med. Times and Gaz.*, 1880) describes twenty-eight cases of atrophied eyeballs, and in speaking of causes, says: "There is strong reason for connecting nearly every case with infectious blood diseases."

De Wecker distinguishes this affection of the vitreous, which he calls "choroiditis metastica," "irido-choroiditis metastica," from irido-choroiditis due to embolus and embolic infarction. Knapp (*Arch. f. Oph.*, Bd. xiii. 1, p. 127) has determined that metas-

tatic choroiditis is an extensive collection of pus between choroid and retina, with a cell growth at the expense of the stroma of the choroid and iris, leading to a considerable thickening of these tissues and thorough infiltration of the retina and vitreous with pus. In vain has he sought for an embolus of the vessels of the uveal tract. This rapid accumulation of pus in the vitreous crowding the normal tissues aside, argues against a parenchymatous purulent degeneration, and in favor of the theory of an abundant filtration through the walls of the vessels of white blood cells under the influence of an infectious substance in the blood. The anatomical examination by Schmidt (*Arch. f. Oph.*, Bd. xiii. 1, p. 18), of metastatic irido-choroiditis, showed no emboli or thrombi underlying purulent degeneration.

Metastatic choroiditis (de Wecker), as met with in inflammation of the cord in the newborn, in severe typhoid, after scarlet fever, erysipelas, cholera, acute rheumatism, and in tuberculosis, owes its causation to the free communication existing between the lymph spaces of the eye and brain, and is dependent on a peculiar condition of the blood in infectious diseases. In its history and pathology it is different from the form seen in puerperal and pyæmic conditions. Panophthalmitis—an inflammation of every part of the eye, as the name implies—need not be mistaken for spontaneous suppurative hyalitis. The inflammatory action is intense, leading to chemosis, necrosis of the cornea, hypopyon, purulent iritis, and cyclitis, and other signs of an acutely destructive process. It is usually induced by a traumatism, occasionally by embolus or metastasis.

The new cases described in this paper, in conjunction with those referred to, afford strong evidence of the possibility of a spontaneous inflammation of the vitreous body. This inflammation may lead simply to a solution and slight loss of transparency of the vitreous, or to its destruction through pustulation, and in either case is independent of the uveal tract. It is analogous to the different forms of superficial and deep ulceration of the cornea. It may be due to various causes, prominent among which is the exhaustion and debility following low fevers. Recognizing this source as important, it behooves those who have such cases to treat to be apprehensive of the complication, and endeavor by frequent testing of vision and the use of the ophthalmoscope, to prevent disastrous results. If the patient complain of failing vision and opacities are seen floating in the vitreous, energetic supporting measures must be resorted to with the hope of preventing degenerative inflammation. If, however, the yellow reflex has appeared in the pupil, there is no possibility of saving the eye, and enucleation should be practised when the patient is able to sustain the shock of the operation.

HOSPITAL NOTES.

TREATMENT OF CHOLERA INFANTUM.

The Thomas Wilson Sanitarium, Baltimore.

Dr. William D. Booker, Physician-in-charge, directs that the patient be made to lie upon the bed, and all unnecessary handling avoided; thorough cleanliness is observed, soiled clothing and diapers being removed from the room at once, and the room kept well ventilated. Care is taken to protect the body from sudden changes in atmospheric temperature, by suitable regulation of the clothing or wrapping.

In the early stage, when there are high fever and frequent vomiting and purging, as little as possible is taken into the stomach; fresh spring water or pieces of ice are given to relieve the thirst, the quantity allowed depending upon its retention by the stomach. Peptonized beef-tea, if retained, is given in teaspoonful doses every three or four hours, and no milk food allowed until vomiting ceases. Fifteen to twenty drops of brandy in a teaspoonful of water are given every two hours, the quantity and frequency increased as the pulse grows weaker.

The bowels are irrigated once or twice daily with two or three quarts of lukewarm water. A Nélaton's catheter attached to a fountain-syringe is introduced gently, and as high in the rectum as possible; the water is then allowed to run into the gut in a gentle and steady stream until it returns clear. The washing out is thorough, and always given by a physician; it has proved most decidedly beneficial in checking the vomiting and purging, and relieving the stupor. Deodorated tincture of opium, or sulphate of morphia with resorcin, is given by the stomach, if not contraindicated by stupor.

In the stage of collapse the extremities are kept warm with hot-water bottles or cotton wadding; poultices of flaxseed meal and mustard are kept over the belly, and stimulation is increased. Aromatic spirits of ammonia is added to the brandy, and, when the collapse is extreme, tincture of musk, or ether, given hypodermatically. When vomiting ceases, a return to milk food is gradually effected. At first teaspoonful doses of peptonized milk, diluted with water, are given at long intervals, and the quantity and frequency very cautiously increased. If vomiting returns, milk is stopped at once.

When reaction comes on, and the heart's action becomes stronger, the stimulation is gradually diminished. If the diarrhœa persists, it is treated with opium and resorcin, alternating with small doses of nitrate of silver by the mouth, and rectal irrigations. The body is sponged daily with warm water and soap. The dusting powder used is composed of lycopodium with four per cent. of salicylic acid. The greatest care is still observed in the diet, and all the minor details of nursing.

The Children's Hospital, Washington, D. C.

Dr. Samuel S. Adams, to quiet the stomachal irritability, prefers creasote or carbolic acid half a drop in a drachm of lime-water every two hours. Rice-water will sometimes be retained when everything else is rejected. Rubefacients of mustard or cloves may be applied to the epigastrium as counter-irritants.

To check the diarrhœa he has found bismuth subnitrate in cinnamon and lime-water the best combination. It must be given in from three to five grain doses every two hours. In some instances, lead acetate, acetic acid, and lime-water, have proved beneficial; this mixture should be rendered perfectly clear by the addition of the acid, otherwise it should be rejected. These mixtures also seem to exert a soothing effect on the irritable stomach. Benefit is not to be expected from the vege-

table astringents. Some have claimed benefit from the starch-water and laudanum enemata, but his experience has been different.

In all cases the condition of the anterior fontanelle is his guide for stimulating. As long as this is depressed he has no hesitancy in continuing or, perhaps increasing, the stimulant, and it is surprising how well infants bear it. He uses whiskey or brandy, and sometimes a little camphor. In too many cases the stimulation is put off until the infant is too ill to absorb it, or harm is done by leaving it to the discretion of the nurse, when too much is given.

When the temperature is very high, he orders occasional spongings with cool water, whiskey and water, or bay rum and water. During the sponging care should be taken to apply cold wet cloths or an ice-bag to the head, which should be changed frequently.

Of the opiates he prefers the camphorated tincture because it is more manageable, more certain in its action, and least likely to do harm of the preparations of opium. If there is any evidence of jactitation or convulsions, he relies on sodium or potassium bromide.

The infant should be kept in the cool air as much as possible; it should be kept upon a pillow, and not in its nurse's arms, and all superfluous clothing should be removed.

Stimulation and external warmth are the indications for the stage of collapse. He gives whiskey or brandy, and sometimes camphor. To excite cutaneous warmth, hot bottles, warm blankets, and mustard foot baths should be applied.

The infant should have small quantities of milk and lime-water at short intervals; cool water and cracked ice occasionally to allay thirst; the stimulant should be gradually withdrawn; sleep must be secured, if necessary, by the camphorated tincture of opium; cool, fresh air should be secured by taking the advantages offered by the city parks, and discretion in bathing and clothing the infant should be exercised.

Home for Sick Children, Cincinnati.

Dr. Forchheimer bases his treatment upon the following principles:

I. Removal of the cause. II. Treatment of digestive symptoms. III. Treatment of general symptoms and complications.

I. The child must be kept cool if the attack occurs in hot weather. For this purpose all unnecessary clothing must be removed; no flannels, no belly-bands. The patient must be kept in the open air—night air is as good as day air. We need reduced external temperature. If the attack occurs in winter, removal from bad hygienic surroundings becomes imperative. When error in diet can be discovered, quantitative or qualitative, the treatment is begun by administering a laxative dose of calomel. This is not done when the diarrhœa is already profuse.

II. The patient is put upon diet, consisting during the first twelve to twenty-four hours of brandy and water. All water given to these patients first to be boiled, then cooled off; the patient to have as much as needed to quench thirst, but in small quantities at a time. This usually controls vomiting, makes the patient comfortable, reduces the quantity of stools, and the brandy, given in full doses, keeps up the patient's strength. Opium is given in small doses, very carefully, and only for relief of great pain or to prevent too great waste from serous discharges. The remedy that has given more satisfaction than any other is salol, gr. ½–j every two to four hours. When vomiting has been completely controlled, *skimmed* milk, well diluted, is given as food. The milk must be tested with litmus paper before it is given, must be administered in small quantities at a time, and frequently. The quantity to be increased, the dilution to be diminished, and whole milk to be given as the patient convalesces. If the infant be at the breast, it should be allowed to nurse at long intervals, and to take as little as possible at a time.

III. Fever is treated by lukewarm baths, given, if necessary, every hour or two. Occasionally benefit is derived from keeping the infant in a continuous lukewarm bath for one or more hours. Cold baths are never used, as being too dangerous in infants. Antifebrin is being used this year with very good results so far. Collapse is treated by the warm mustard bath, the mustard to be mixed in a small bag of old muslin or linen with cold water, the bag and the baby to be put into the water together. As soon as the attendant's arm, holding the child in the water, begins to tingle from the mustard, it is time to remove the patient. The child is then wrapped in a blanket and bottles with warm water placed around it. All this can be done in the open air if found necessary. In addition, the patient is stimulated by the internal administration of ether, in full doses, musk, or brandy. The ether is given in milk, and repeated frequently. If vomiting continues, hypodermatic injections of ether are given.

Convulsions are treated variously, depending upon their cause. If early in the disease, they are due either to high temperature or blood poisoning. In the first instance antithermic and antipyretic remedies are used; in the second, rectal injections of chloral hydrate. If recurring late in the disease, they are usually caused by disturbance of blood supply to the brain, lack of oxygen, increase of carbonic acid, thickening of the blood within the brain, thrombosis. This form of convulsion cannot be treated with any satisfactory results. Free stimulation is usually indicated.

It goes without saying that the above is to be treated as an example to which there are many individual exceptions.

West Side Dispensary, Chicago.

Dr. J. Suydam Knox treats a case of choleraic diarrhœa with vomiting as follows: Immediately two to five grains of calomel are administered to remove fermenting ingesta. Then bismuth subnitrate and cerium oxalate in full and oft repeated doses for the vomiting and diarrhœa. Cold baths, spongings, or pack for fever and restlessness. In rapid cases, or in collapse, hypodermatics of morphia sulphate, and alcohol or ether; also aromatic spirits of ammonia in ice water for the extreme thirst.

He believes that there is neither digestion nor assimilation during the attack, therefore no food is given. He allows an abundance of ice water for the thirst, and to compensate for the excessive drain of fluids. As soon as the stomach will tolerate food, albumen water and beef peptonoids are given in small quantities, often repeated.

University of Michigan, Ann Arbor.

Dr. Victor C. Vaughan, up to the beginning of the summer of 1886, in his treatment of the choleriform cases, did not restrict the use of milk, and he employed subnitrate of bismuth, pepsin, chalk mixture, and the camphorated tincture of opium, with a dose of castor oil in those cases in which serous discharges had not already appeared, and with astringent enemata of either tannic acid or nitrate of silver in some instances. This treatment was eminently unsatisfactory. A large majority of the violent cases terminated speedily and fatally.

In June, 1886, he began the *no milk* treatment. The prohibition of milk was absolute. If the child was taking a part of the nourishment from the mother's breast, this source of supply, as well as the cow's milk, was forbidden. No prepared food containing milk, or to which milk should be added, was allowed. The child was given a little barley or rice-water, and some meat preparation, as beef-tea or chicken-broth. The only prepared foods which he used at all were the peptonoids of Reed & Carnrick, and the peptone of Rose, and, with the exception of the objection to the taste of the peptone manifested by a number of the children, he was much pleased with these meat preparations. The medicinal treatment was the same as it had been in preceding years, and as given above. Out of twenty-two cases of the choleriform type treated by this method last summer, three died. This, in view of his past experience, was very gratifying. All the cases were severe, and the three deaths occurred within twenty-four hours after the appearance of the first symptoms One of the children had, some three weeks after its recovery, a second attack, when it came under the care of a physician who prescribed one of the infant foods with milk; this time the result was fatal. But this number of cases is too small to draw any positive conclusions from. However, the success seems large when compared with his earlier experience.

MEDICAL PROGRESS.

Why are Preparations of Digitalis Frequently Inert?—Kobert, of Dorpat, answers this question as follows in an article reporting a number of experiments upon digitalis, in the *Therapeutic Gazette* of June 15, 1887: "What form of digitalis shall be employed? Most commonly preferred is the infusion. This naturally contains only those substances soluble in water. Of the three important active principles digitalein, a drug which produces dilatation of the vessels of the kidneys, is soluble in alcohol, it is contained in the tincture and alcoholic extract. The other constituents, digitoxin and digitalin, are also soluble in alcohol; in alcoholic preparations, as well as in the leaves themselves, we obtain the three important active principles. In fluid extracts digitoxin is precipitated as an insoluble powder. Acetum digitalis (vinegar of digitalis) approaches the infusion most closely in regard to its contents. It is very desirable that fresh, well-dried leaves be used. When the leaves are imperfectly dried, a species of fermentation may occur which may decompose the three essential components of the drug, for digitalin and digitalein are, like all glucosides, decomposable through foreign matter and fermentation. Digitoxin is, however, not a glucoside, but decomposes as easily and under the same circumstances as the others. The result of the decomposition of digitalis is not a substance producing the desired effects upon the heart, but a resin, digitaliresin (from digitalein and digitalin) and toxiresin (from digitoxin). The effect of these bodies is a violent irritation of the convulsive centres of the brain; severe convulsions may also occur, as in poisoning with picrotoxine or cicuta verosa. Whenever the usual effects of digitalis are wanting, or instead cramps occur, we are safe in thinking that the preparation used was a poor one. The decomposition of digitalis may occur not only in the leaves, but also in infusions and solutions of digitalin and digitalein. As Tardieu says, 'The pure digitalein when suspended in water or dissolved, undergoes decomposition in a short time, whereby the bitter taste is altered, and, as an indication of a radical change in the constitution of the drug, gases form.' Among my patients I have very often seen decomposition in preparations of digitalis which had stood two days in a room. This happens from the mixing of digitalis tincture with syrup or watery solution. The practice prevalent in America of not preparing the drug from the leaves when desired, but of using a concentrated infusion, explains the frequent disappointment in its use."

The Relief of the Dysuria and Strangury of Old Age.—Fischer has found the following pill useful:

℞.—Ext. nucis vom. . . . . gr. 8.
Liquiritiæ . . . . . q. s.
Ft. pil. 50 in num.
Sig. Two pills on retiring.

—*Deutsche medicinische Wochenschrift*, June 16, 1887.

Simple Amygdalitis and Bicarbonate of Soda.—Rovira y Oliver, of Barcelona, has reached the following conclusions regarding this subject:

1. The simple forms of amygdalitis are superficial from the beginning to the end, or superficial in the beginning, but soon advancing until they become parenchymatous; or they are deeply seated from the commencement.

2. The anginæ disappear within twenty-four hours by dietetic means.

3. The application of bicarbonate of sodium, over a superficially or deeply inflamed tonsil, by neutralizing the acidity and retention of the mucus discharged by the follicles, does not fulfil more than a secondary indication.

4. In this manner bicarbonate of soda may expedite the cure of catarrhal and parenchymatous tonsillitis.

5. Bicarbonate of soda cannot be relied upon as an abortive method of treatment of anginæ of the first group.

6. The action of the soda salt is not efficacious in impeding anginæ of the second group—the advance of the catarrhal to the parenchymatous state.

7. When the stroma of the gland has been affected, bicarbonate of soda can produce a cure in from three to seven days.

8. These effects of bicarbonate are attained by making the applications every two or three hours.

9. It is useless, and may even be dangerous, to apply it, as Dr. Giné recommends, every five minutes.

10. A few styptic drugs, such as sulphate of alumina, are more efficacious than bicarbonate of soda.—*Journal of Laryngology*, June, 1887.

Sixty Cases of Extirpation of the Uterus for Cancer.—Fritsch reports sixty cases from his clinic at Breslau, with a mortality of seven, about ten per cent., from the operation itself. Twenty patients are without a return of the disease, of whom two were operated on three years ago; seven more than two years ago; while the remainder were without a return after the first six months, which Fritsch considers the most dangerous time. He concludes that uterine carcinoma returns less frequently than carcinoma in other localities, and thinks the reason lies in the anatomical relations of the lymphatics of the uterus.—*Centralblatt für Chirurgie*, June 18, 1887.

Death from Tight Lacing.—A sensational illustration of the fatal effects of tight lacing, was afforded last week by the death of a single woman, aged fifty-two, who died quite suddenly in the street. Mr. A. A. Varne, the house-surgeon of the Northwest London Hospital, to which institution the lifeless body was taken, stated that the deceased was a woman who laced very tightly, so much so that she could hardly breathe, and it was owing to the impossibility of proper expansion of the lungs that syncope had been produced. Two years ago he had been called to her in the street; she had fallen down and "broken a bloodvessel." Here is a text which popular health lecturers will be able to use effectively, it may be hoped, and—we fear—for many a long day.—*British Medical Journal*, June 25, 1887.

A Convenient Food for Children.—Marteneau describes the following food, which may be used whenever farina and like foods are indicated.

Farina (Indian corn)	5 parts.
Powdered cocoa	1 part.
Sugar, in the form of vanilla powder	3 parts.

Of this, between three and four ounces may be used in twenty-four hours; it may be prepared by boiling for five minutes in milk. The nutritious substances contained are fat derived from the corn; the butter of cocoa, and phosphate of lime from the grain.—*Revue de Thérapeutique*, June 15, 1887.

A Treatment for Diphtheria.—Kaczorowski reports the following treatment as having been useful in his hands:

It is necessary to consider two factors in the treatment of diphtheria, viz., the local affection, and the consecutive septicæmia. The former is dependent upon specific bacilli, and presents no danger so long as it remains localized. Danger only commences when the infiltrated parts soften and ulceration is produced. At this period the Streptococcus pyogenus of Rosenbach appears, and is propagated throughout the organism. Therapeutics must be directed to limitation of the local process, and to the avoidance of all means which could irritate the mucous membrane and produce collateral inflammation. The author employs the solution of chloride of sodium, 1 per cent., with tincture of iodine, 0.5 per cent.; at first given in doses of a spoonful every half hour, and when improvement appears, every two hours. Under this treatment the false membrane and the infiltration gradually disappear without further trouble. The author employs the same solution as a gargle. Immediately ulceration and signs of general infection appear the author administers alcohol and aromatic remedies, externally and internally. Of these remedies the author gives the preference to camphor and benzoic acid.—*Journal of Laryngology*, May, 1887.

Modified Laryngectomy.—Dr. J. Solis-Cohen describes the following operation in the *New York Medical Journal* of June 18, 1887:

1. Make an incision from the hyoid bone to the lower border of the cricoid cartilage, and exactly in the middle line.

2. Carefully separate the sterno-hyoid muscles.

3. Hold the soft parts aside and insert, from above, one blade of a strong cutting forceps with narrow blades beneath one wing of the thyroid cartilage, one-fourth of an inch from the angle of junction with its fellow, and sever the cartilage vertically its entire length through to the crico-thyroid membrane.

4. Make a similar cut on the opposite side.

5. Seize the freed angular portion of the thyroid cartilage, comprising its entire respiratory contingent, with a volsellum forceps, and draw it to either side, the soft parts being separated meanwhile from the inner surfaces of the detached wings of the thyroid cartilages with the handle of the scalpel.

6. Make a transverse cut to sever the cricoid cartilage from the trachea. (At this step, in the living subject, a sterilized cotton plug should be inserted into the upper end of the trachea, preliminary tracheotomy having been performed previously.) (If the cricoid cartilage is to be retained, disarticulate the arytenoids, and then sever the soft parts above the cricoid instead of below. This modifies the next step in the procedure accordingly.)

7. Lift the cricoid cartilage forward and carefully separate it with the edge of the knife from the inferior cornua of the thyroid, laterally and superiorly, and then from the œsophagus posteriorly.

8. Insert a finger into the pharynx from below and carry its tip over the epiglottis to draw that structure down.

9. Divide the thyrohyoid membrane and the fibrous tissues still holding.

10. Lift out the exsected respiratory portion of the larynx.

The arteries likely to require ligation will comprise small branches of the superior, middle, and inferior laryngeals.

Upon the living subject the operation should be strictly aseptic, and where practicable should have been preceded by several days by a preliminary tracheotomy. The trachea may be occluded superiorly by a small rubber bag attached to the smallest-sized soft catheter, introduced through the tracheal wound, above the canula, and then inflated. The canula may be temporarily removed during the introduction of the bag and its inflation.

Advantages alleged for this procedure:

1. Its rapidity, ease, and comparative safety to the patient.

2. The small size of the wound.

3. The preservation of the attachments of the thyrohyoid ligament and the greater part of the membrane, and of the thyrohyoid, sternohyoid, stylopharyngeus, and inferior constrictor muscles; leaving—

4. Important functional structures retained in their normal relations for deglutition; and leaving—

5. A firm, natural support for the adjustment of artificial substitutes for the larynx.

For these reasons it is submitted that this procedure should be preferred to complete laryngectomy whenever not precluded by extent of disease.

PIMENTA (ALLSPICE) IN THE TREATMENT OF RHEUMATISM.—POULET has made a liniment by combining capsicine, the active principle of the plant, with liquid ammonia, when a soapy liquid results. The following are the proportions:

Pimenta	ʒ 6¼.
Ammonia	ʒ 3¹s.
Essence of thyme,	
Chloral hydrat.	āā ʒ 2½.
Alcohol (60°)	1 quart.

The allspice should be macerated in alcohol for a month, to which the ammonia is added. The chloral and thyme are added after expressing all fluid from the allspice, and the liquid kept in a hermetically sealed bottle. The substance so prepared is called *apone*, and may be used for friction about diseased joints; it may be used pure or mixed with olive oil. Internally from 10 to 20 drops of a tincture of pimenta may be taken in water or cold tea.—*Journal de Médecine*, June 19, 1887.

ACTINOMYCOSIS IN A GARDENER.—A case of actinomycosis occurring in the human subject is reported by Dr. Hanken, of Dortrecht, which appears to belong to what Dr. Israel classes as cases of migration of fungi through the mouth and pharynx. The patient was a gardener, aged thirty-four, who had nothing to do with the care of cattle. He applied for advice on account of long-standing dyspepsia. It was observed that there were four tumors on the lower jaw, situated between the left mental foramen and the angle of the jaw. They were movable and somewhat elastic on palpation. The teeth were fairly healthy, with the exception of the four second molars, all of which were carious; the roots, however, could be palpated without causing pain. The diagnosis appeared to lie between gummata and cold cutaneous abscesses due to irritation from carious teeth in a tuberculous subject. No sign or history of syphilis could be made out, so it was decided to draw the two diseased molars on the left side, open the tumors and scrape them out with a sharp spoon. The contents were found to consist of a viscous chocolate-colored fluid, in which opalescent granules, the size of a pin's head, were suspended; these proved, on microscopic examination, to be actinomycetes.—*Brit. Med. Journ.*, June 25, 1887.

THE TREATMENT OF CHRONIC URTICARIA.—MUSSY recommends the following:

℞.—Jaborandi pulv.,	
Ext. guaiac.	āā gr. 1½.
Lithii benzoat.	gr. 3.

For one pill.

Two in twenty-four hours for those suffering from chronic rheumatic urticaria.—*L'Union Médicale*, June 16, 1887.

HYPNOTISM IN MIDWIFERY.—In the *Gazette des Hôpitaux*, M. DUMONTPALLIER reports a case of delivery during hypnotic sleep. The patient, a young woman, aged twenty-four, was admitted into the Pitié Hospital in the sixth month of pregnancy, in order to be treated for pains in the uterus. The patient was easily thrown into hypnotic somnambulism by pressure on the vertex and by verbal suggestion; these measures were of themselves sufficient to relieve her pain. Later on, in the beginning of labor, hypnotism was again tried. The uterine contractions took place about every ten minutes, and lasted from one minute to one minute and a half. During somnambulism the patient distinctly felt the contractions, but said they were not painful; when not under hypnotic influence, however, the pains became intense, and she begged to be put to sleep again. Toward the end of labor the pain became so severe that it was found impossible to keep her in a state of hypnotism. During somnambulism the contractions were more powerful and shorter; the interval between them was only four minutes. M. Dumontpallier reserves his opinion as to the effect of somnambulism on the frequency and force of the contractions, and on the duration of labor. While the patient was in that condition she was perfectly conscious, and talked freely with the people about her. In making a comparison between the analgesia produced by somnambulism and that by chloroform in midwifery, the author states that they differ only in the fact that under chloroform cutaneous sensibility remains intact, while in the somnambulistic state it is extinguished.

PROSTITUTION AND INSANITY.—At the first (Moscow) congress of Russian Alienists, DR. PRASKOVIA N. TARNOVSKAIA, of St. Petersburg, communicated (*Vratch*, No. 9, 1887, p. 216) the results of the anthropometric examination of fifty habitual prostitutes, who had all been inmates of brothels for a period of not less than two years. For the sake of comparison he examined in the same way fifty peasant women of the same age, and, as far as possible, of the same intellectual development, etc. The results of this—probably unique—investigation may be summed up as follows: 1. The prostitutes presented a shortening, amounting to half a centimetre, of the antero-posterior and transverse diameters of the skull. 2. As many as 84 per cent. of habitual prostitutes showed various signs of physical degeneration, such as irregularity in the shape of the skull, asymmetry of the face, anomalies of the hard palate, teeth, ears, etc. 3. In 82 per cent of the prostitutes the parents were habitual drunkards. 4. In 18 per cent. of cases the prostitute examined was the last survivor of a large family of eight to thirteen children, all of whom had died at an early age. 5. These facts afford grounds for the belief that prostitutes, as a class, furnish the largest contingent of subjects predisposed to nervous and mental affections. There is no special work in any language on this subject, nor are there any statistics as to the number of prostitutes yearly admitted to asylums. Dr. Tarnovskaia urges the desirability of collecting such statistics for the purpose of determining the

part which professional prostitution plays in the causation of mental and nervous disease.—*British Medical Journal*, June 4, 1887.

An Application for Pruritus of the Vulva.—Mènière advises the use of the following:

R.—Zinc. oxid. . . . . ʒ ij½.
Potass. bromid. . . . . ʒ ij½.
Ext. cannabis indic. . . . . gr. 30.
Glycerite of starch . . . . . ʒ j½.

To be preceded by cold bathing.

When complicated by acne, applications of very cold infusion of black tea are useful.—*L'Union Médicale*, June 4, 1887.

Eberth's Rods in Typhoid Stools.—In the *Vrach*, No. 22, 1887, p. 438, Dr. G. O. Shpolansky, of the Odessa Town Hospital, writes that he and Dr. N. A. Stroganoff, prosector of the same hospital, have examined bacterioscopically stools in ninety-six cases of enteric fever, with the object of solving the following two questions of paramount practical importance: 1. Whether Eberth's microbes are present in all cases of the disease or not? and 2. Whether the microbes are still present in the stools of convalescent patients? The main outcome of their researches may be summarized thus. The typhoid bacilli were found in 90 of 96 cases. Of those examined, 88 recovered and 8 died. In one of the latter no bacilli could be detected in the stools during life. In one of three convalescent patients examined no bacilli were found after the temperature had finally returned to the normal range. In the remaining two the microbes were still daily discovered for nine and fifteen days respectively after the defervescence. In view of the facts stated under the first head, a bacterioscopic examination of the stools should be undertaken in every case where any suspicion as to typhoid fever may arise; and in consequence of those adduced under the second, the stools of the patients recovering from enteric fever cannot be considered innocuous for at least fifteen days after the defervescence.—*British Medical Journal*, June 25, 1887.

Tincture of Green Soap as a Vehicle.—Unna, of Hamburg, in the *Monatshefte für Dermatologie*, No. 11, recommends this tincture originally advised by Hebra. He uses the following formula:

Sapon. virid.	100 parts.
Alcohol (95 per cent. or absolute)	50 parts.
Oil of lavender	½ part.

This solution dissolves, in equal weights, chloroform, ol. terebinthinæ, pix liquida, æther petrolei, benzin, æther; of carbon disulphide two-fifths weight at body temperature is dissolved. The utility of this vehicle to dermatologists is apparent.

Fluorides of Ammonium and Iron in Hypertrophy of the Spleen.—Dr. Lucas reports in the *Practitioner* for June, 1887, his researches with these remedies as follows:

The fluoride of ammonium crystallizes in hexagonal prisms, dissolving readily in water, and the solution is colorless, but it acts on glass (for chemical reasons which I need not enter into here), going through it and escaping. To prevent this escape the expedient of coating the inside of the bottle with wax, so as to prevent the unstable compound in solution from coming in contact with glass, has to be resorted to; or the solution may be kept in India-rubber tubes or gutta-percha bottles. I adopted the first-named plan, and did not cause more of the solution to be made than was actually wanted for use. The strength of the solution employed by me was four grains to the ounce. Of this liquor ammonii fluoridii I began with five minim doses, diluted in an ounce of water, and administered thrice a day, after meals; and the dose, after a day or two, may be increased to 8 minims, then to 10, 12, 15, 18, 20, and so on, at intervals of a few days, the increase being effected gradually and cautiously; the great point to attend to is to insure the taking of this medicine after food, as otherwise gastric and intestinal irritation will be set up, while with this precaution it will be found to be fairly well tolerated in the majority of cases.

Certain physiological effects, more or less common to all the cases, were observed. Briefly, there was a marked influence on the blood-pressure, which had a downward tendency at first; the pulse fluctuated, and the number of beats was lessened. It was also found that the drug possessed antipyretic properties when the temperature ranged above the normal point, and it prevented attacks of ague, thus proving it to be an anti-periodic. In all the cases it produced nausea at first, though gradually a sort of tolerance appeared to have been established, and the drug could be borne in much larger doses. It produces some intestinal irritation, probably acting more on the duodenum, and giving rise to some diarrhœa. I am not sure that it has any action as a hepatic stimulant. The appetite, after a time, improves under its use. Almost all the patients complained of a pricking or twisting pain or uneasiness in the spleen itself, the original pain being sometimes aggravated. When given carefully and after meals, which should be the invariable rule, it is better borne and does not produce nausea and purging to the same extent. It certainly seems to excel any other method of treatment with which we are acquainted. Although I began with small (5 minim) doses, I should be disposed to start with 20 or even 30 minims diluted in an ounce or two of water, and administered always after a meal. The combination of iron with hydrofluoric acid, I am inclined to think, would prove more valuable on account of the hæmatinic properties of the former, and because as an adjunct it would exercise its astringent and tonic influence on the mucous lining of the stomach and intestines, and thus in a great measure tend to counteract the unpleasant effects complained of, and perhaps also to augment the evident specific action on the spleen. The fluoride of quinine can easily be prepared, and so, also, can the triple fluoride of iron, quinine, and ammonium.

Hyoscine as a Hypnotic.—Kobert, of Dorpat, concludes from his studies of the action of hyoscine on the brain of normal men, that it is a feeble hypnotic which has no such influence over animals. In cases which other narcotics fail to affect, the repeated injection of $\frac{1}{100}$ to $\frac{1}{75}$ of a grain caused sleep and quietude without ill after effects.—*Deutsche medicinische Wochenschrift*, June 9, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE. . . . . $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

PHILADELPHIA.

SATURDAY, JULY 23, 1887.

THE RESULTS OF PYLORECTOMY.

CONSIDERABLY more than one hundred cases of pylorectomy have been performed since Pean, in April, 1879, first demonstrated that a patient could survive some days after such a mutilation, and Billroth, that recovery was possible under the same circumstances. Since then various opinions have been held in regard to the justifiability of the operation, and in regard to the benefits to accrue from it; and carefully prepared articles have appeared in different lands and languages, in which the indications and contra-indications, the operative technique, complications, and the percentages of deaths and recoveries have been critically studied; but until recently sufficient time had not elapsed in which to learn the final results of the operation. Six years have now passed since the first successful cases were reported, and we are able to form a tolerably accurate idea as to the indications for the operation, the rate of mortality, and the final results in those cases which recovered.

The indications for the operation have been stated to be carcinoma of the pylorus, cicatricial stenosis, hemorrhage from the stomach, and perforation of the stomach, but only the first two need claim our attention at this time.

The pylorus has been excised for cancer many more times than for any other cause, and the death-rate is about 75 per cent., whilst that for cicatricial stenosis, whether from an ulcer or from the ingestion of caustic liquids, is about 50 per cent. The mortality of 103 cases of all kinds, collected by Richter, in August, 1886, was 72 per cent., and this percentage remains about the same in each series of statistics which have been published. In the hands of individual operators the mortality is not so great, thus the death-rate in Billroth's clinic has been 55 per cent., according to von Hacker, in his monograph, "Ueber die Magenoperationen an Prof. Billroth's Klinik, 1880, bis März, 1886." Not only, however, is the mortality much greater in the case of cancer than in that of cicatricial stenosis, but there is a great difference in their final results. There is no case known to us in which a radical cure has resulted from excision of the cancerous pylorus, death taking place in from four months to five years from a recurrence of the disease, either *in situ* or in more or less remote regions. Of 15 cases in which recovery occurred, 2 died four months subsequently, 2 in six months (one of these, however, succumbed to pneumonia), 1 in eight and a half months, 1 in ten months, 3 in twelve months, 1 in fifteen months, 2 in two and a half years, 1 in three, and 1 in five years, and 1 patient is reported alive at the expiration of two years. There is probably no case in which a permanent cure has been effected where the disease was cancer, the longest period of life having been five years and three months. In four or five cases of which we have knowledge, the patients were restored to a tolerable degree of usefulness, the gastric distress relieved, and normal digestion attained for a period of more than two years, and about an equal number for twelve or fifteen months, but the immediate mortality of the operation is so enormous, that the small respite enjoyed by the few scarcely counterbalances it. It must be confessed, however, that the future of the operation does appear to be rather less gloomy than it was some time ago.

In regard to resection for non-malignant stenosis, the matter is placed in much more favorable light, since those cases which do not succumb to the operation are permanently cured. At the recent Congress of German Surgeons, RYDYGIER, of Culm, reported the further progress of two cases, in which he had performed pylorectomy for ulcer. One of these, a woman, had survived nearly six years, had borne two girls, and was in good health at that time, another was alive when last heard from, about three years having elapsed; and a man upon whom Billroth had operated was in the enjoyment of perfect health at the expiration of three years. Rydygier advocates the operation in the case of ulcer of the pyloric end of the stomach, but this certainly does seem to be a severe and dangerous method for a non-malignant disease. If the ulcer was not situated exactly at the pyloric opening, it would seem to admit of some other treatment, either excision or cauterization with the thermocautery; whilst, if the pylorus was the first affected, a partial resection might be done. For cases in which cicatricial stenosis has occurred, we think the favorable results of

digital division, as practised by Loreta, demand earnest consideration, as the mortality is very much less and the results appear to be good. In a case of cicatricial stenosis, Mikulicz made an incision in the length of the canal, and united the incision in the transverse direction, which had the effect of widening the strictured opening; but, unfortunately, the patient died on the third day of collapse. Heineke had also previously adopted this method.

An observation of Kocher's indicates that the dangers of pylorectomy do not cease with recovery from the operation, nor with the escape from recurrence of malignant disease, since in two cases upon which he had successfully operated, one died six months and the other three years subsequently, with decided symptoms of a fresh stenosis. This is a new experience, and may be due to the peculiar method of operating employed by this surgeon, in which the edges of the incisions were crushed with forceps previous to uniting the stomach and duodenum. Woelfler, on the other hand, stated that in his case, which survived five years after the removal of a scirrhus of the pylorus, there was no stenosis: the entrance into the duodenum was funnel-shaped, and pervious for the thumb, a four millimetre mucous fold occupied the seat of junction, whilst externally the seat of operation was no longer recognizable, and the sutures were not to be found.

Before leaving this subject, we wish to call attention more earnestly to the operation of gastro-enterostomy, or the formation of a fistula between the stomach and jejunum. It has been performed but a few times, and generally for inoperable carcinoma: but as it is easier to perform than resection, takes less time, and is not followed by so much shock, it certainly deserves a greater trial than has been bestowed upon it. It must be remembered that neither operation is radical, but only palliative, hence that which exposes the patient to the least risk ought to be given the preference. Hahn, of Berlin, expresses this same view, when he says the operation is a good one in certain cases, and is the operation of the future. He performed gastro-enterostomy on a man over two years ago, on account of carcinoma of the pylorus. The man was forty-six years of age, and had emaciated rapidly; and nothing appeared to pass the pylorus. Gastro-enterostomy was performed, and the patient gained fifty-four pounds in weight, ten of which were gained in three weeks. He was still alive and following his work when the case was reported.

In conclusion, we may state that pylorectomy is fatal in the proportion of about 75 per cent. in the case of carcinoma, and that of the 25 per cent. which survived the operation, death has occurred from recurrence in one year or under in 60 per cent., and that, as far as appears at present, not a single case has been permanently cured. In consideration of these facts, well may we pause before subjecting a patient to this dangerous procedure. We have long been impressed with the idea that gastro-enterostomy was indicated much more frequently than pylorectomy, an opinion which is held by Hahn also. The mortality after resection for cicatricial stenosis is about fifty per cent., and as these cases are radically cured, it is certainly permissible to operate, though the Loreta operation ought to be carefully considered.

THE DANGERS OF ANTIPYRIN.

Apropos of the several editorials which have recently appeared in The News on the subject of antipyretics, it seems proper to call attention to the possibility of untoward symptoms being produced by at least one of them. While it is possible for any drug to produce evil effects when used in excess, there are some drugs which seem to bring about disagreeable consequences in those who by reason of idiosyncrasy are affected by small doses, as violently as the average person would be by an enormous amount.

As has already been pointed out in these columns, antipyrin is a very safe remedy, very few people having an idiosyncrasy in regard to its action, but, nevertheless, it is but right and proper that instances where its influence has been for harm rather than good, should be brought before the profession. Several instances in which cardiac failure and collapse have come on, have been reported, both in this city and elsewhere, within the last two or three years: and very recently, in the *Journal de Médecine de Paris* of May 29, 1887, attention is again called to the subject by the report of the case of a young woman, in the eighth month of pregnancy, who suffering from an attack of typhoid fever, accompanied with hyperpyrexia, was given cold baths for the reduction of the temperature. She was also given fifteen grains of antipyrin in divided doses. In a short time the temperature fell below normal, there were vomiting, cyanosis, hesitating and embarrassed respiration, and absolute relaxation, and collapse. The patient, however, recovered.

The action of drugs on persons readily affected by them, owing to idiosyncrasy, is so commonly met with, and yet so little understood, that it is impossible for the practitioner to be aware of such cases unless previous experience has taught him that any one patient belongs to this class, and it is the duty of every one to record such cases, since it is only by this means that we can obtain information which will aid us in laying down preventive rules.

It has been abundantly proved, both by the bedside and in the laboratory, that antipyrin is not a cardiac depressant, yet cases of cardiac depression

apparently from its use have certainly been reported. An important point as to the use of antipyrin in fever is that moderate doses will generally accomplish all that is desired, and we cannot help feeling that in many instances direct injury is produced by a disregard of this fact.

It has been proved by investigators that antipyrin in very large doses, instead of stimulating the inhibitory heat-centre, and thereby decreasing the production of heat, paralyzes it, and thereby causes an enormous rise of temperature, so that it is possible that in some of the cases reported, in which the temperature rose rather than fell, the dose of the drug was too large. On the other hand, it is easy to understand how in susceptible persons the inhibitory heat-centre may be so stimulated by a small dose that the production of heat falls below the dissipation, with a consequent lowering of bodily temperature and a necessary collapse. It is always advisable to give antipyrin, therefore, in small doses at first, in order to avoid dangers from idiosyncrasy and overaction of the drug; ten grains, we believe, will accomplish, as a general rule, all that we have been accustomed to expect from twice or thrice this amount.

FŒTAL MEASUREMENTS.

MOST obstetric authorities have taught that there is no difference in size between the male and the female pelvis at birth; in other words, that there is an entire absence of sexual characteristics. So, too, it has been claimed that the head of the male fœtus is larger than that of the female, the general size of the fœtuses being the same.

The recent measurements of thirty-three infants made by FRASCANI, however, prove that these statements are erroneous. Thus, while he found the biacromial diameter about the same in the two sexes, the bistrochanteric and the bisiliac are greater in the female. He also found that in the male and female fœtus, of equal weights, the head diameters corresponded, and hence the opinion sustained by Sir James Y. Simpson, among others, that labor in case the child is male, will be more difficult because its head is larger, falls to the ground, for the labor is no more hindered than if the child were female, and of equal size.

It is to be hoped that Frascani's investigations will be continued by others, and if confirmed they will not only show quite conclusively that there is no difference between the sexes so far as original brain endowment is concerned, but also that nature begins in intrauterine life the preparation of the female pelvis for childbearing.

IPECACUANHA IN LABOR.

CARRIGEI, in the *Revue Médico-Chirurgicale des Maladies des Femmes* of May 25th, states that from the remarkable influence ipecacuanha has over uterine hemorrhage he has been led to employ it as an oxytocic. He claims that it stimulates the uterus, and at the same time facilitates dilatation of the rigid os; under its use uterine contractions, hitherto very painful, but without effect upon the os, become changed, so that they have an active, expulsive character, and cause less suffering. The quantity advised is a grain and a half to three grains of the powdered root.

This practice is by no means new, though the quantity of the medicine advised is much less than that heretofore employed; we have known of the remedy being used more than thirty years ago in cases of tedious labor in the first stage, the delay resulting from a rigid os, and it was given in doses of five grains every ten minutes until decided nausea, if not actual vomiting, resulted. The beneficial result was attributed, not to any special action upon the uterus, but to the relaxation of the os which usually occurs in consequence of great nausea. But probably the treatment was never very generally followed, and has fallen into disuse. It certainly will be a very great gain if, with so simple a remedy, and in so small a dose, the first stage of labor prolonged by a resisting os, and attended with severe suffering, can be shortened and the pain lessened.

THE Medical Department of the University of Vermont held its Thirty-fourth Annual Commencement last Monday, and the degree of M.D. was conferred on fifty-three graduates.

THE toy pistol has this year, as formerly, occasioned not a few deaths by tetanus. A case recently came to our knowledge where a lad of twelve years died at the end of ten days after he had shot himself in the hand with one of these toys. The wound appeared to be slight, and the parents did not think it necessary to summon surgical aid until tetanic symptoms manifested themselves. It is to be hoped that the time will soon come when the manufacture and sale of these deadly playthings will be suppressed by the strong arm of the law.

A PRIZE of $5000 is offered by the Grocers' Guild of London, for an original discovery in sanitary science. The successful essayist is expected to discover a method by which vaccine may be cultivated apart from the animal body without loss of potency. The prize is known as the "Quadrennial Discovery Prize," and the subject above indicated is the same as that which was proposed during the four years, 1883–1886, and which failed of solution by any of the competitors. Competing essays will be received from any source, and must be forwarded on or before

December 31, 1805, to the Worshipful Company of Grocers.

With profound regret we record the death of Dr. Joseph C. Hutchison, which sad event occurred at his residence in Brooklyn, on July 17, 1887, the result of renal disease, with complications of both cardiac and pulmonary sequelæ. Dr. Hutchison was the son of Dr. Nathaniel Hutchison, formerly of Booneville, Missouri, and he was born in that State in 1827. He graduated in medicine at the University of Pennsylvania in 1848, and spent the first four years of his practice in his native State, after which he removed to Brooklyn, where he soon enjoyed an extensive hospital and private practice, and was called upon to perform the most important and difficult operations of surgery. He was Professor of Operative and Clinical Surgery in the Long Island College Hospital for several years, and enriched surgical literature by numerous valuable contributions. He was the founder of the Brooklyn Orthopædic Infirmary, and its chief surgeon for many years.

As a physician he was distinguished for his study of cholera, having had charge of the Brooklyn cholera hospital during the epidemic of 1854; he had been also Health Commissioner of Brooklyn for several years.

Dr. Hutchison held positions of honor in the medical societies of Brooklyn and vicinity; he was a Fellow and formerly Vice-President of the New York Academy of Medicine, member of the New York Pathological Society, of the American Surgical Association, attending surgeon to the Brooklyn City Hospital, and consulting surgeon to the Kings County, St. John's, and St. Peter's hospitals. He was the President of the Long Island College Hospital, and ex-President of the Medical Society of the State of New York.

He was the author of a school text-book on physiology and hygiene, and a frequent contributor to the medical press. As a surgeon he enjoyed an international reputation. Very positive in his opinions, he was slow to assert them, and firm in convictions, he was tolerant of the views of others.

He was universally honored and esteemed, and his death is mourned alike by the profession and by his fellow-citizens.

Dr. Ariel Ballou, one of the oldest and best known physicians of Rhode Island, died at Providence, on the 15th inst., aged eighty-two years. He was born in Cumberland, R. I., his father having been a Revolutionary soldier. He was, for a time, a student at the Berkshire Medical Institute, but was graduated from the Bowdoin Medical School, in 1830. Beginning practice at Woonsocket, R. I., he soon rose to the front rank of his profession, where he remained for nearly fifty-five years. About two years ago he withdrew from practice and removed to Providence.

Dr. Ballou was a man of genial, yet commanding, presence, and few men have been more highly honored and esteemed than he was, both as a physician and a citizen. He was President of the Rhode Island Medical Society in 1855–56, and one of its Censors ever since. He was a member of the General Assembly from 1842 to 1852, and introduced the bill for the abolition of capital punishment. He was President of the Board of Trustees of the Harris Institute, and of the Board of Corporators of the Woonsocket Hospital. In the Masonic order he had advanced to a high degree, being Past Grand Master of Masons of Rhode Island.

Dr. Ballou will long be remembered by his younger professional brothers as a most earnest, dignified, and honorable promoter of the interests of medical science and practice.

REVIEWS.

The Practitioner's Handbook of Treatment, or The Principles of Therapeutics. By J. Milner Fothergill, M.D., Physician to the City of London Hospital for Diseases of the Chest, etc. Third American from the Third English Edition. Pp. 660. Philadelphia: Lea Brothers & Co., 1887.

Dr. Fothergill is always interesting and instructive, and in this standard work he shows his peculiar power as a writer on therapeutics to the best advantage. Everything he undertakes is done conscientiously, and if at times he is not truly sound in the doctrines which he advocates, he, nevertheless, always commands our respect and attention.

The present edition, besides being carefully revised, has been enlarged by two chapters—one on "The Dietary in Acute Disease and Malassimilation," and one on "The Management of Convalescence," and is nearly one hundred pages larger than the first edition. A few years ago, in reviewing the first edition of this work, we took occasion to criticise the author's opinion on some subjects, especially that on the non-nutritive value of beef-tea. In confirmation of the view then expressed we have since found abundant experimental proof that this preparation is nutritive, and, therefore, not useless as a food.

In the Chapter on "Assimilation" the author evidently shows that he is not quite up in the latest work on the physiology of digestion, when he says (page 39) that "The first great function of the liver is to form glycogen from the sugar and peptones supplied to it from the intestines." We think it is now about two years since Hofmeister demonstrated that the peptones disappear in, and are absorbed by the white corpuscles of the intestinal mucous membrane, in the same manner as the oxygen of the air unites with the hæmoglobin of the red corpuscles, and are by them probably converted into some other form of albumen, since their identity as

peptones is lost here, and practically, therefore, they cannot reach the liver.

In regard to the artificial digestion of foods, we hardly think it advisable to commend the method so strongly as the author is inclined to do. Digestion is not such a simple function as it is believed to be, and since there is at present such a tendency to substitute the artificial for the natural it is well enough to take a conservative position on this question until its utility is proved beyond a doubt.

In conclusion, we would say that the book well sustains the favorable impression which it created at the beginning of its career, and in its present improved form will be welcomed more than ever by the busy practitioner and the scientific student of medicine.

CORRESPONDENCE.

ANTIFEBRIN AS AN ANODYNE IN SPINAL SYPHILIS.

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS of June 11, and in the *British Medical Journal* of the same date, reference is made to Germain Sée's observations on the analgesic action of *antipyrin*. Dr. C. W. Suckling, in a note to the latter journal, states that he has tried antipyrin in "three cases of locomotor ataxia, in which the pains were severe, with relief in each instance," and "in one case, with complete abeyance." He states also that Lépine has found that *antifebrin* relieves the pain in this disease. Germain Sée, however, state that *antifebrin* is inefficacious as an anodyne in doses of less than eight grains, and that it is dangerous in larger doses than this, it having been found that larger doses sometimes cause grave alterations in the blood, converting the hæmoglobin into metahæmoglobin (*L'Union Médicale*, April 26, 1887), and for these reasons he prefers antipyrin, the use of which is not attended, in his opinion, with equal disadvantages.

The same objection, viz., that a condition of cyanosis is sometimes caused, has also been urged against antipyrin, and I think that in the employment of both these drugs we should keep a careful lookout for the occurrence of symptoms pointing to imperfect oxygenation of the blood. I have given antifebrin to perhaps twenty patients suffering from typhoid fever and from the hectic fever of phthisis, and have rarely found it necessary to exceed five grains at one dose, in order to get a decided effect from this drug.

In the case of spinal syphilis, to which I now refer, the pains, which were severe, yielded to five grain doses of antifebrin. The pains were due, I believe, to gummatous infiltration of the posterior columns of the spinal cord. The patient contracted syphilis twenty-two years ago, and when I first saw him, ten years after the primary lesion, he complained of severe intercostal pains; so, even at that time, it is probable that there had been some infiltration of the spinal cord. A few months later *right* optic atrophy occurred, and hearing in the *left* ear became much impaired. At about this time paralysis of the facial muscles and hemianæsthesia of the tongue occurred. In 1880 he had a fall on his head, and, a little while later, was found to be suffering from mental aberration and was treated for some months at the Insane Department of the Philadelphia Hospital, and, later, at the Norristown Asylum.

In 1881 there was marked paresis of the left leg, and severe intercostal and girdle pains were complained of. Under specific treatment, the pains diminished in severity, but, since another attack of left hemiplegia last autumn, they seem to have occurred more frequently and with greater severity. They were described as sharp, cutting pains, and extended from the upper intercostal spaces to the sacrum and also along the course of both sciatic nerves, more particularly the left. There has been, at no time, any paralysis of the bladder.

On June 22d, having administered several quarter-grain doses of morphia with the effect of giving him only temporary relief, I ordered him antifebrin (grs. v) to be taken whenever pains were particularly severe. One week later patient stated that he had not felt so well for a year. The first powder checked the pain in less than half an hour. When the pains recurred they seem to have been less violent, and, each time, five grains of antifebrin sufficed to check them, and so, after five days of this treatment, and after taking forty or fifty grains of antifebrin, patient is, temporarily at least, entirely free from pain.

July 8th. Patient has had slight recurrence of the pains during the past week, but they were apparently far less severe than they were before. No sweating and no prostration were caused by these doses.

Yours, etc.,

HENRY M. FISHER.

PHILADELPHIA, July 11, 1887.

A LETTER FROM STRASSBURG.

Septic Cyst in the Abdomen—Removal of the Ovaries for Myoma—Phosphorus in Rachitis.

THE most interesting case of the past week in any of the clinics here, was in the gynecological clinic of Prof. Freund. The patient was thirty-one years old, married, and the mother of three children. The family history was good, except that a grandmother had died with tuberculosis.

Two years ago the tumor was accidentally discovered by a physician who was called to prescribe for some derangement not dependent upon the presence of the growth. At this time she was pregnant and passed through her pregnancy and confinement without mishap. The tumor, however, began to grow very rapidly, and several weeks after confinement it was tapped and three quarts of light straw-colored fluid withdrawn. No accident or bad effect followed this puncture, but before many months had passed, the tumor began to grow again. The patient became pregnant and was delivered at term—three months and a half ago. The tumor again began to grow rapidly and became so large that the physician again punctured it, five weeks post-partum. The contents were of the same character as at the time of the first tapping, but the result was different. The canula infected the tumor and suppuration within the sac resulted. It filled again in a very short time and the patient had fever and chills. Her physician determined to insert a canula, and leaving it in situ to wash out the sac every day, which he accordingly did nineteen days before she was brought to the hospital. But

unfortunately the canula must have slipped out of the cyst and remained buried in the abdominal wall, where the injections of iodine were consequently made, causing the formation of a large abscess cavity, which had dissected its way between the layers of the abdominal wall. This canula was left in for two weeks and the injections made with great regularity. But as the patient's condition was rapidly growing worse, she was finally sent to the hospital. Her temperature varied between 38° and 40 C. Her strength was gone. The abscess in the abdominal wall was discharging an exceedingly offensive pus. Her face wore an anxious expression, and she seemed to all to be on the brink of the grave.

Prof. Freund very soon decided that delay would be fatal, and that her only chances lay in an immediate operation, which he proceeded to perform by opening the abdomen in the linea alba below the umbilicus. The abscess was in the side and toward the crest of the ilium. The tumor was found closely adherent to the anterior abdominal wall throughout the entire length of the incision, which was then immediately lengthened upward until the upper edge of the tumor had been passed and it was possible to get into the abdominal cavity. Then began a most tedious dissection. The adhesions anteriorly to the abdominal wall were carefully broken through. The abscess was now found to have no connection whatsoever with the tumor. The omentum, small intestine, sigmoid flexure, and uterus were all intimately adherent to the tumor. Finally the pedicle was reached. It was twisted several times upon its long axis and a fold of small intestine was twisted with it and adherent to it. The contents of the tumor, which was semi-solid, were offensive in the extreme. A large mass of necrotic tissue was found in the cavity surrounded by fluid and gas, the result of the infection and consequent putrefaction. The intestine and colon wherever their peritoneal covering had been torn loose in the dissection, were now covered with peritoneum as far as possible by means of catgut sutures, the pedicle carefully ligated, the opposite ovary, which also contained several small cysts, removed, and the abdomen closed after irrigation with a solution of salicylic acid.

Toward the close of the operation the patient was in a very bad condition. The shock of such a tedious, protracted operation threatened to prove fatal, but she was almost instantly relieved by a rectal injection of hot red wine with a few drops of the tincture of opium. The result of this injection was simply marvellous; pulse and respiration improved in a very short time, and the abdomen was rapidly closed without any provision for drainage. The abscess was opened, its walls scraped out with the sharp spoon, and dressed with iodoform.

The next morning there was no fever and the only unfavorable symptom was the chloroform vomiting, which, however, ceased in the afternoon. The second and third day passed without an unfavorable symptom. The further course of the case will be reported in my next letter.

Prof. Freund accounted for the twisting of the pedicle by the fact that the patient had been pregnant twice, and that the tumor was probably turned partly around by the increasing size of the uterus as the pregnancies advanced on the one hand, and by its rapid diminution in size after the birth of the children on the other. The intestine was probably adherent and so was drawn around after the pedicle.

A slight parotitis with some fever was the only interruption to an otherwise rapid recovery. Such triumphs as this, are, unfortunately, not common, but the very fact that success is possible even in the face of such unpromising conditions as existed in this case is encouraging to those who are reluctant to accept the responsibility of advising any interference in desperate cases. The possibilities of abdominal surgery have long since exceeded the limit which only a few years ago could not have been passed without exposing the operator to criticism.

Judging from the past, it is confidently to be expected that this field must still be enlarged in the near future, and this operation is significant of the direction in which this enlargement is gradually taking place—*i. e.*, the indication for operating to combat septic inflammatory processes of and within the peritoneal cavity.

The same operator recently removed both ovaries from a patient in the thirties, on account of a large intramural myoma of the uterus. The almost continual hemorrhages had so weakened her that she was unable to attend to her household duties. A vaginal examination revealed a tumor which gave an indistinct fluctuating sensation to the finger, and which from its position in the left side of the pelvis so concealed the left ovary that the presence of the latter could not be determined. A positive diagnosis was, therefore, not made, but from the clinical history a uterine tumor was thought probably to be present.

The operation, which was performed in the new hospital, was conducted under the most careful antiseptic rules. The operating room, with its polished hard wood sides and tiled floor, kept scrupulously clean and neat, is certainly a model chirurgical work-room, and offers no congenial resting-place to septic germs. The few invited guests were politely requested to cleanse their hands in a disinfecting solution, and to clothe themselves in a long linen garment before entering into this temple of cleanliness. The only exception was in the case of three students who appeared in full evening dress. Prof. Freund remarked, that clinical teaching to a large class is impossible in abdominal surgery and, therefore, he has the students come in small divisions in order that each one can see every step of at least one operation. It is true not only of abdominal surgery but of all other branches, that students profit but little from surgical clinics as far as the minutiæ, upon which everything depends in so many cases, are concerned. The science of surgery can be taught to large classes but the art cannot be.

The bleeding and oozing in the incision through the abdominal wall was completely controlled before the peritoneal cavity was opened. The exploration of the cavity revealed a tumor, soft but not fluctuating, in the uterine wall. The right ovary was normal, but the left one was enlarged, and in the left Fallopian tube a small cyst was found.

The right ovary was first removed. Its base was securely ligated by transfixing the broad ligament immediately beneath it in several places with a needle threaded with silk. The base thus perforated was first ligated in sections, and then *en masse* in the usual manner. The ovary was now cut away, leaving a large

stump above the ligatures. The operator now pressed all of the fluids out of the tissues in the stump by means of a sponge, in which it was entirely enveloped. When the sponge was removed the stump remained a moment colorless, but as the vessels filled with blood the pink color gradually returned, and a few drops of blood appeared upon the cut surface. A new ligature was thrown around and tied very tightly, the stump again pressed out, and the same manœuvre repeated, until finally it remained entirely bloodless.

The stump was now secured in a clamp with broad flat arms (Langenbeck's) about a fifth of an inch above the line of the ligatures, the tissues above the clamp seized with a pair of toothed forceps, and cut off with the thermocautery, which was passed along the surface of the clamp. This process left a short stump, securely ligated, from whose surface no oozing could possibly take place. The left ovary and the small cyst near it were removed separately in the same manner. The incision was closed with wire and silk sutures, without drainage. The patient made a prompt recovery without a single unfavorable symptom.

In the Children's Clinic here they do not make as favorable a report of the action of phosphorus in rachitis as has come from other sources. The rachitic material here, as in other unhygienic and overcrowded European cities, is very large. Phosphorus was tried perseveringly, as it is claimed, without an improvement in any case that might not as well have been attributed to the improved diet and hygienic surroundings which the hospital offers to the little unfortunates who find their way within its portals.

Phosphorus has proved, in some hands at least, of the greatest value in this disease. The results are not, as a rule, as prompt as the first publications gave reason to expect, but they are, nevertheless, undoubted, and when the cases have not gone on too far, may be confidently expected. Your correspondent can refer to the records of a Children's Polyclinic which will corroborate all of the above, and which will probably, in the near future, be published.

NEWS ITEMS.

Dr. C. B. Nancrede, of Philadelphia, is delivering the Course of Lectures on Surgery at Dartmouth College, in the absence of Dr. P. S. Connor, who has gone to Alaska on a journey undertaken to restore his health.

The Exposition of the Hygiene of Infancy at Paris.—This exposition was opened, on June 24th, by an address from its president, the recitation of a poem, and by music from the Guard of the Republic. It embraces all possible appliances for maintaining the lives of infants, and all substances and articles known to be of value in treating the diseases of infancy.

During the exposition open conferences will be held morning and afternoon, the first of which will be reserved for mothers. Vaccination will be performed every Monday.

Exhibition at Wiesbaden.—A scientific exhibition will be connected with the Sixtieth Congress of German Naturalists and Physicians, to be held in Wiesbaden from the 15th to the 24th of September. It will be strictly scientific, not mercantile, and its purpose will be to show at a glance the latest and most perfected instruments and apparatus which have been placed at the disposal of science and medicine in the last few years. The following groups will form part of it: surgery, physical diagnosis, and therapeutics; ophthalmology, gynecology; laryngology, rhinology, and otology; orthopedics, dentistry, chemistry, instruments of precision, with subdivision for microscopy; instruments and apparatus aiding instruction in natural history, geography, equipment for scientific travel, photography, anthropology, biology and physiology, hygiene, electro-therapeutics and neurology, and pharmacology.

The Vienna General Hospital.—Hofrath Dr. Hoffmann having retired from the post of Director of the General Hospital, Vienna, Professor Böhm has been appointed to this most important office, the said hospital being, we believe, the largest hospital in the world.

The charges recently made against this hospital in the Austrian Parliament were not sustained upon investigation.

Opposition of the Russian Government to the Study of Medicine by Women.—Not content with closing the academies for women at St. Petersburg, Moscow, and Kiew, the Russian Government has increased the tax for passports to students going to study in Switzerland (which offers excellent advantages to women), from ten to twelve roubles monthly, a sum which will make it impossible for many poor women to study medicine.

Vacation Classes at Vienna and Berlin.—The programme of medical courses of instruction at Vienna during the months of August and September has been issued. The number of such classes is now very large, and of their convenience for foreigners there can be no question. Most of them are complete within a month, meetings being held daily. Amongst them may be noted those on morbid anatomy (Dr. Adolf Zemann); pathological histology (Dr. Kolisko); bacteriology (Prof. Weichselbaum and Prof. von Frisch); medical diagnosis (Drs. von Frisch and E. Neusser, Drs. Bamberger and Lorenz, Drs. von Langer and Heitler, and Dr. Drozda); diseases of the organs of circulation (Dr. Bettelheim); diagnosis of brain and spinal cord diseases (Dr. Benedikt); and the pathology and treatment of nervous diseases (Prof. Rosenthal). There are also courses on forensic medicine, urinology, practical and operative surgery, ophthalmology (no fewer than seven different courses), gynecology, laryngoscopy, otology, dermatology (Prof. Kaposi and Dr. Riehl), syphilis, etc. An even more complete series of post-graduate classes of a like kind will be held in Berlin, from the 26th of September to the end of October, of which the announcement will be found in the *Berliner kliniker Wochenschrift* of June 27, p. 483.—*Lancet*, July 2, 1887.

A Parallel to Guiteau's Case.—M. Deny, one of the physicians to the Bicêtre, while making his rounds on June 17th, was attacked by an insane patient, who attempted to stab him in the abdomen with a sharpened

table-knife. The attack was fortunately frustrated. The same patient, in November, 1885, demanded from de Freycinet the payment by the Government of a considerable sum in recompense for the death of a child in Panama. He was examined and pronounced insane, his malady being characterized by ideas of grandeur, persecution, refusal of a just claim, and revenge, similar to those which led Guiteau to assault the President. When questioned, he avowed his determination to repeat the assault.—*Le Progrès Médical*, June 25, 1887.

Paralysis from Earthquake Electricity.—The Paris correspondent of the *Lancet* of June 11, 1887, writes as follows regarding a case resulting from the earthquake at Nice: "Dr. Onimus relates a case of nervous disturbance (Société de Biologie) of unusual interest. The subject was a strong, vigorous man, not easily impressionable, and incapable of deceit. He was at the time in charge of a fort. There were, it will be remembered, three distinct commotions, the strongest at six, another soon after, and a third, much weaker, at nine o'clock. The patient was sending a telegraphic message, and, happening to have two points in contact with the metal of the transmitting apparatus, felt a violent shock, and lost consciousness for ten minutes. During the remainder of the day he felt giddy and weak, but has no recollection of *phosphènes* at the occurrence of the shock. Two months later he complained of constant headache, and fibrillary contractions in the muscles of the limbs. The right arm was paretic, and the extreme weakness was confirmed by the dynamometer. Besides tremor and painful localizations along the median nerve, there was a considerable decrease of sensibility, the finger-tips scarcely recognizing a separation of twelve millimetres between the points of the compass. The paralysis of the face was on the left side, and consisted of ptosis, accompanied by blepharospasm. This crossed or alternate paralysis is what is seen constantly as a result of a powerful electric shock; but in this case the symptoms have been more serious and persistent. At the present time there is little if any improvement."

The Sweating Sickness in France.—There can be no doubt that the epidemic which has broken out in the Departments of Vienne, Haute-Vienne, and Indre, is an idiopathic miliary fever, the historical sweating-sickness. Dr. Daremberg has written an important letter on the subject to the *Journal des Débats* (June 25th). He has accompanied Drs. Chantemesse and Thoinot to Montmorillon, the centre of a district where more than 4000 cases, with 300 deaths, have occurred. The disease is characterized by a profuse sweat, and an eruption of small miliary vesicles. M. Littré believed that the disease was known to Galen, but the first authentic epidemic was the *Sudor Anglicus*, "Sweating-sickness," or *Suette Anglaise* of 1485, well known to historians. It was very fatal, according to Delaune, in London in that year, and Stow records that in 1499 it raged in the metropolis, so that Henry VII. and his court removed to Calais. In 1506 and 1507 the epidemic was terrible; Oxford was depopulated. In 1529 an epidemic ravaged Europe. In the seventeenth century it appeared in France and Germany; the mortality was less, but the miliary rash appeared in every case, whilst in the first epidemic it was rare. But Dr. Daremberg shows that the patients in the English epidemic of 1485 mostly died within a few hours of the appearance of the first sweat, before the rash had time to develop. Precisely the same thing has occurred this year, several patients having died in two or three hours without any trace of rash. In the same district very mild cases have occurred, the patients being confined to their beds for a couple of days and then able to work. As in an epidemic in Poitou in 1843, and another in the Aude in 1864, the epidemic was preceded by many cases of eruptive diseases mistaken for measles. The troops of the garrison of Poitiers suffered severely from this "scarlatiniform measles." The first case of sweating-sickness this year occurred on April 16th in the commune of Saulgé. In the town of Montmorillon (5128 inhabitants), 47 persons died of the epidemic between May 3d and June 19th. At Moulismes (940 inhabitants), there have been 45 cases and 16 deaths—the mayor, two other officials, and the wife of one of those magnates dying within a few hours. At St. Remy (893 inhabitants), there have been over 50 cases. In five or six communes, hardly a dozen people have escaped infection. The more recent cases have been mild. Dr. Daremberg found that the patients had little pyrexia, dyspnœa, or palpitations. They had profuse perspiration and an eruption, in some cases resembling measles, in others scarlatina, but always vesicular. The vesicles on the tongue formed ulcers. The patients felt no prostration and little loss of appetite. The earlier cases were of quite a different type. The patients showed the worst symptoms of malignant fever, profound depression, violent delirium, syncope, epistaxis, and intestinal hemorrhage. A great number of intermediate forms proved the identity of the very bad and the very mild cases. The alleged anomalous forms of measles seen in the same district are also forms of sweating-sickness. Drs. Brouardel, Chantemesse, Descout, and Thoinot have inspected the infected communes, and enforced, through the sanitary authorities, disinfection by means of sulphurous and carbolic acid. The peasants at first objected to these measures, and dreaded the damage which the acids might inflict on their furniture. They preferred the common French placebo, infusion of lime-tree blossoms, to quinine; and when stricken, they closed their windows and piled eiderdown quilting and blankets over their bodies, notwithstanding the intense heat of the weather and the fetor developed by the practice. Dr. Daremberg believes that the disease is infectious. Another medical correspondent, signing himself "Dr. G. D.," writes to the *Journal des Débats*, noting the fetid perspirations, the measles-like variety, and the extreme infectiousness of the disease. Some recent cases of so-called measles at Bourges appear to him to be sweating-sickness. "Dr. G. D." reports that the activity of the sanitary authorities is rapidly extinguishing the epidemic. We trust that it may only reach this country in the form of abstract discussion at the Epidemiological Society or elsewhere; fortunately it is very unlikely to cross the Channel, or even to reach Paris.—*British Medical Journal*, July 2, 1887.

From *Le Progrès Médical* of July 2, 1887, we learn that this disease is decreasing, and that physicians have been sent from the Paris hospitals into the infected districts.

Smallpox Hospitals.—One of the important subjects connected with sanitary administration is the location of smallpox hospitals in towns and cities. For the sake of the patients who are removed to these institutions, it is very essential that the distance which they are transported should be as little as possible; while, on the other hand, for the protection of the public, such hospitals should be situated so far from the inhabited portions of the towns as not to be a factor in the spread of the disease. Mr. W. H. Power, a medical inspector of the English Local Government Board, has given especial attention to this subject, and the evidence accumulated by him seems to indicate that a smallpox hospital in a town causes a greater incidence of smallpox in the vicinity. Within an area contained by a circle described three-quarters of a mile from the West Ham smallpox hospital, the death-rate from this disease was never less than twice, and sometimes even ten times, greater than the general rate; the number of cases showing a progressive decrease as the distance from the hospital increased. Mr. Power has studied the theories that the wind was a factor in this increase of cases near the hospital, and that the nurses and others were the channel of communication, but has found them inadequate to explain all the facts.—*Science*, May 20, 1887.

A Popular Remedy for Ivy Poisoning.—A writer in *Popular Science News* for June, 1887, says as follows:

I have always been extremely susceptible to the poison of poison ivy and oak so as to give me great annoyance, unless it is immediately checked on its first appearance. This common washing-soda accomplishes for me, if properly applied. I make the application by saturating a slice of loaf-bread with water, then cover one surface with soda, and apply to the eruption, the soda next the flesh. When the bread is dried by the animal heat, I drop water on the outer side so as to keep it thoroughly moistened, and dissolve the soda crystals in contact with the skin. This, you will perceive, is merely a bread poultice; the bread being a vehicle through whose moisture the soda reaches the humor. I find that the washing or bathing with soda water, even continuously, will not suffice with me. My skin requires the heat and moisture of the bread in order for the soda to act on and neutralize the poison. I rarely have need to retain this soda poultice for more than thirty minutes on any affected part. No pain ensues. Formerly I suffered often for weeks, as the poison would spread all over my body. Now thirty minutes measure the duration of its exhibition.

French Laws and Usage Regarding the Insane.—The case of Baron Seillière, who spent some time in the United States, has attracted considerable attention to the French laws regarding the adjudgment and incarceration of the insane. The Paris correspondent of the *Lancet* writes as follows, under date of July 2d:

"A well known member of society, Baron Seillière, has been somewhat hurriedly transferred to the *maison de santé* (as lunatic asylums are more discreetly termed in France) of the celebrated Dr. Falret. A sharp controversy has arisen in the press in consequence of this sequestration, and many of the writers are loud in denouncing the state of the law on the subject, and in abusing all those concerned in administering it. Baron Seillière bitterly complains of the whole proceedings. He declares his family laid a plot to entrap him. 'I may have been eccentric, I may have spent money freely, but many a man in my position has done the same. If I have made bad speculations, I have also made successful ones, and as I neither think, speak, nor write as a madman, I consider myself the victim of an unjustifiable attack.' On the other hand, Professor Charcot, who has interviewed the patient on behalf of his family, declares him to be insane. As I have already hinted, the comments of the press upon mental physicians and their doings are far from complimentary; and although there is no doubt a great deal of exaggeration some of the statements made are not entirely devoid of foundation. It is an aphorism amongst French alienists that any person in Paris presenting signs of excitement should, in the absence of a satisfactory explanation, be suspected of general paralysis. Not only are the Parisians privileged in counting in their number the highest percentage and the most eminent sufferers from the *maladie du siècle*, but it is said also that Paris has a special attractive influence for general paralytics as a class. Given, then, a person in a state of excitement, he would, if he had the misfortune to be examined by an expert, run a very fair chance of being sent to an asylum. Once there, any explosion of indignation would be taken as additional evidence of the necessity of the measure, and if the victim were not calmed by being cut off from the world, and soothed by the application of a *camisole de force*, no sane alienist would entertain any further doubt as to the nature of his case. The lawyers maintain, and this is the practical outcome of the whole matter, that the *affaire Seillière* shows the urgent necessity of a change in the present law concerning the insane. As it is, they say, once a man has fallen into the hands of the alienists, the machinery of the law is powerless to help him. He may, at the discretion of his keepers, be separated from the whole world, and even subjected to solitary confinement. Should those interested in his welfare think they have cause to complain, they are hardly able to obtain an independent examination. Those who have the patient in charge can refuse access to all except the expert commissioned by the courts in each particular instance; but as in lunacy practice the expert of to-day is often the alienist of to-morrow, the patient may benefit but little by such a consultation."

A Movable Sheet for the Sick.—Dr. Roche describes the following device in the *Popular Science News* for May, 1887: I have found the following a valuable arrangement for the sick needing change of position, or, as is often the case, a weak nurse to perform the labor, or in cases of surgery, where the safe and easy movement of the patient is necessary:

Fasten smoothly to the mattress, with strong safety-pins, a rubber blanket or piece of enamelled cloth, rubber or enamel side up. Upon this, place a similar rubber or enamelled cloth, if possible somewhat wider, so as *always* to keep the under one covered. Cover with a sheet, and make up the bed as usual. Between the rubber or enamelled surfaces sprinkle soapstone powder, kept by all shoedealers, or glove-powder; or,

if nothing better can be had, the common graphite, known as stove-polish, will do. Now, by grasping the edge of the under sheet and upper enamelled cloth at the same time, it will be found easy to *roll over* or move the heaviest person with slight effort, and little pain or straining, either to nurse or patient.

If the device prove too slippery when not wanted, a few strong pins fastening it to the bedding beneath will prove sufficient to prevent it.

A CLERGYMAN'S VIEW OF THE FAITH AND MIND CURES.—The faith cure and the mind cure are at the present time attracting a great deal of popular attention; and almost daily cures are announced, under this treatment, of persons who have, under all other methods, remained chronic invalids. It is not to be wondered at, that physicians denounce this treatment as charlatanism, but it was hardly to be expected that one of the most potent arguments against the validity of its claims should come from one of the clergy. In a recent sermon on this subject, Rev. E. C. Ray, of Hyde Park, Ill., says, "Apparent cures are often followed by a relapse, temporary improvement by permanent decline. From reported cases of cure we must deduct many of unreported relapse: it is not in human nature, when a wonderful cure has been published abroad, to follow it up with an account of the relapse coming afterward. Mistaken diagnosis accounts for many supposed cures. Physicians often, patients more often, mistake the nature of a disease. Temporary swellings are called malignant tumors or cancers (thus cancer doctors get their reputations); hysteria simulates almost every other disease, so as to deceive even the most elect of doctors; dyspepsia produces symptoms of heart disease or other deadly illness. There can be no question that a large proportion of faith cures and mind cures, and a considerable proportion of cases under ordinary medical treatment, are cases of mistaken diagnosis, the disease being less serious in its nature than was supposed. Mistaken prognosis accounts for many cases; mistake as to what would be the outcome of the disease if no curative methods were employed. It is a truth seldom recognized by patients, though well known to physicians, that in most cases not hopelessly fatal from the start, there is from the start a strong tendency toward recovery. Dr. Austin Flint, Sr., than whom perhaps no abler physician has lived in this land, always urged upon his students the truth that not drugs, but *vis medicatrix naturæ*, the healing power of nature, is the means of recovery. The wise physician and nurse seldom attempt more than gently and humbly to assist Nature in her curative processes. Let me add the statement of a conviction derived from some years of such close scrutiny of medical practice of various schools as a pastor has good opportunity for—a conviction agreed to, I think, by most physicians. The benefit of medicine is often not its direct action upon the disease or upon the body, but its action upon the mind, and through that upon the nervous system and the whole body, stimulating faith, hope, expectation of recovery, good cheer, which are probably nature's mightiest remedial assistants."—*Science*, May 27, 1887.

ELECTRIC ENDOSCOPES.—At the late German Congress of Surgeons, NITZE, of Berlin, and BRENNER, of Vienna, exhibited electric endoscopes which had been proved successful in the examination of the interior of the bladder.

MAREY'S ODOGRAPH.—MAREY, of Paris, has invented an apparatus for recording and estimating the speed of a man's walk, and the course taken by a man or group of men. The apparatus is not yet perfected, but it will be applied to the study of many physiological problems connected with the conservation of human energy in which accurate observation is desired.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JULY 12 TO JULY 18, 1887.

MATTHEWS, W., *Captain and Assistant Surgeon.*—Assigned as member of Army Retiring Board, at Washington, D. C.—*S. O. 159*, par. 2, *A. G. O.*, July 12, 1887

SKINNER, J. O., *Captain and Assistant Surgeon.*—Relieved from duty.—*S. O. 159*, par. 2, *A. G. O.*, July 12, 1887.

MAUS, L. M., *Captain and Assistant Surgeon.*—Ordered to accompany the Eleventh Infantry in changing station from the Department of Dakota to the Department of the East.—*S. O. 158, A. G. O.*, July 11, 1887.

PERLEY, H. O., *Captain and Assistant Surgeon.*—Ordered to accompany the Eleventh Infantry in changing station from the Department of Dakota to the Department of the East.—*S. O 158, A. G. O.*, July 11, 1887.

GARDNER, E. F., *Captain and Assistant Surgeon.*—Ordered to accompany the Twelfth Infantry from Madison Barracks to Duluth, and to return with the Eleventh Infantry.—*S. O. 143, Division of the Atlantic*, July 13, 1887.

EBERT, R. G., *Captain and Assistant Surgeon.*—Will, in changing station from Fort Hamilton, New York Harbor, N. Y., to Fort Custer, Montana Territory, accompany the Twelfth Infantry from the East to the Department of Dakota.—*S. O. 159. A. G. O.*, July 12, 1887.

WALKER, F. V., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for four months.—*S. O. 160, A. G. O.*, July 13, 1887.

CABELL, JULIAN M., *First Lieutenant and Assistant Surgeon.*—Ordered for duty as medical officer at Department Rifle Camp, near Bellevue, Nebraska, August 1st, next.—*S. O. 66, Department of the Platte*, July 8, 1887.

A board of medical officers, to consist of *Major and Surgeon* J. S. BILLINGS, *Captain and Assistant Surgeon* W. MATTHEWS, and *Captain and Assistant Surgeon* F. C. AINSWORTH, is constituted to meet in this city, for the examination of a candidate for admission to the Medical Corps of the Army.—*S. O. 157, A. G. O.*, July 8, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JULY 16, 1887.

LONG, W. H., *Surgeon.*—Granted leave of absence for thirty days, on account of sickness, July 12, 1887.

AUSTIN, H. W., *Surgeon.*—Granted leave of absence for thirty days, July 16, 1887.

WATKINS, R. B., *Assistant Surgeon.*—Relieved from duty at Marine Hospital, Detroit, Michigan; ordered to assume charge of service at Evansville, Indiana, July 9, 1887.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

LOCAL TREATMENT OF DISEASES OF THE BRONCHIAL TUBES AND LUNGS.[1]

BY BENJAMIN F. WESTBROOK, M.D.,

PHYSICIAN IN CHIEF TO THE DEPARTMENT OF THROAT AND CHEST DISEASES, ST. MARY'S HOSPITAL, BROOKLYN; PRESIDENT OF THE BROOKLYN PATHOLOGICAL SOCIETY.

THE object of this paper is to describe some of the methods which I have employed in the local treatment of chronic bronchitis, chronic interstitial pneumonia with bronchiectasis, and phthisis pulmonalis, and to give the results which have been obtained.

CHRONIC BRONCHITIS.

This disease has been treated by three principal methods: First, by the direct introduction of coarse spray into the air-passages by means of Sass' spray apparatus; second, by the inhaling apparatus of Dr. George A. Evans; and third, by the pneumatic cabinet.

In the use of the direct spray, the principal indications watched for have been the amount and violence of the cough, the amount and character of the expectoration, and the presence or absence of emphysema and asthma. When the cough is severe and spasmodic, the treatment is usually begun by the use of sedative substances, particularly carbolic acid and the fluid extract of hyoscyamus. In using the carbolic acid our custom is first to spray the air-passages with a solution equivalent to that of Dr. Dobell, the formula is:

R.—Acid. carbol. cryst. . . .	♏xx.
Sodii bibor.	ʒij.
Sodii phosph.	ʒij.
Glycerini	℥i.
Aquæ	ʒvj.—M.

After first cleansing the nasal passages by the use of this spray, the patient is directed to draw out the tongue and take a deep inspiration, during which the spray is thrown into the pharynx, or directly into the larynx by a bent tube, during two or three successive inhalations. A fifty per cent. solution of carbolic acid in glycerine is then added to the fluid in the flask until the point of tolerance of the patient is reached, and, when as strong a solution as can be borne is obtained, the air-passages are sprayed with this five or six times, the patient always inhaling as deeply as possible. If the necessity for it exists, the nasal catarrh is then treated by such application as seems to be indicated. This method of treatment is repeated every day or every other day, as often as is convenient for the patient, no home treatment being employed, though usually some remedies in the way of tonics or alteratives are used internally at the same time.

By this thorough cleansing and disinfecting of the air-passages, combined with the anæsthetic effect of the carbolic acid, the irritation is usually very markedly allayed, so that for twenty-four hours, at least, after the treatment, the cough is diminished in frequency and violence. The method is not always efficacious. It is sometimes necessary to rely, to a great extent, upon sedative drugs, particularly at the ontset of the treatment, where the spasmodic character is very well marked.

If the treatment by carbolic acid is inefficient, or if the results come about slowly, fluid extract of hyoscyamus may be either added to or substituted for it, the passages being first cleansed and disinfected by means of the alkaline and carbolic acid solution. A spray of hyoscyamus of the strength of about half a drachm to the ounce is introduced, the application being repeated half a dozen times at each sitting. This solution is particularly efficacious where a tendency to asthma exists.

When there is a very copious secretion of muco-purulent matter, stronger astringents have to be employed. The principal of these are tannic acid, the iron salts, and the fluid extract of pinus canadensis. For the use of tannic acid a standard solution is used as the basis.

R.—Acidi carbol. cryst. . . .	♏xv.
Glyceriti tan.	ʒijss.
Aquæ menth. pip. . . .	ʒvss.—M.

After the preliminary step of cleansing and disinfecting, this solution is sprayed directly into the air-passages. When the patient has become accustomed to its effects by one or two inhalations, glycerite of tannin is added to it until it is as thick as it can be and be capable of producing a spray.[1] This spray is then inhaled five or six times. Its effects are often very salutary, the amount of expectoration decreasing perceptibly after each sitting, though the treatment is immediately followed by an increased expectoration, which lasts for from one to three or four hours.

Of the iron salts, I have most frequently employed the chloride, using a mixture of equal parts of the tincture of chloride of iron and glycerine. This is diluted to about twenty-five per cent. and used in the same way as the tannin. Where great relaxation

[1] Read at the meeting of the American Climatological Society, Baltimore, May 31, 1887.

[1] The addition of only a very small amount of water is necessary to render the glycerite of tannin sufficiently fluid to produce a spray with a pressure of forty to fifty pounds. Five or six drops of water to a fluid-drachm give a good spray, and ten drops to a drachm make it capable of being sprayed at quite a low pressure—*i. e.*, fifteen or twenty pounds.

and an anæmic condition of the mucous membrane exist, it acts better than the tannin solution. A solution of iron alum of the strength of fifteen grains to the ounce may also be used. Pinus canadensis is of service in about the same class of cases as are benefited by tannin, though it has rather more sedative effect than the latter. The preparation usually employed is a mixture of equal parts of Kennedy's white fluid extract and glycerine. The liquid is very heavy and can only be sprayed with a high pressure. To use any of these substances most effectually, it is necessary to have a pressure of from forty to fifty pounds to the square inch. This is obtained by the use of the Crown Gas Engine, manufactured by the National Meter Co., 252 Broadway, New York.

A large tank is connected with the gas engine, which has, by a special contrivance, been converted from a water into an air pump, and the compressed air from the larger reservoir is drawn off into an ordinary office receiver at the convenience of the operator. I usually have a pressure of from fifty to sixty pounds to the square inch in the larger reservoir, and, by means of stopcocks, can regulate the pressure in the small office receiver to which the gas is attached, according to the requirements of the case under treatment. Where the nasal passages are very much inflamed and tender, and particularly where there is stenosis, which increases the friction to a high degree, it is better not to go beyond thirty pounds at the beginning of the treatment; but when the swelling of the turbinated bodies and septum has been sufficiently reduced to admit of the free access of air or spray, the passages can be much more thoroughly cleansed and disinfected if we use a pressure of from forty to fifty pounds.

I think it possible that one cause of the avowed failure of certain gentlemen who have recently written upon this subject, to treat successfully nasal catarrhs with the spray, is to be found in the low pressure which they have employed in the introduction of the spray into the nostrils. The degree of pressure required in a given case can be determined in two ways. In the first place, by the amount of resistance which the spray encounters in passing through the nose. This is quickly shown by the regurgitation of the fluid through the nostril into which it is introduced, and its failure to pass through and out at the opposite side. The second are the sensations of the patient, though the latter generally depend upon the former.

Where the nostrils are sufficiently patulous to admit the spray readily, so that there is little tendency to friction or the development of high pressure in particular localities of the nose, the pain is usually very slight, and a high pressure may be advantageously employed. But where the stenosis is well marked, and the friction consequently very great, there is a tendency for the fluid to accumulate or to be forced violently into the chamber of the antrum, and the pain is sometimes very severe. Under such circumstances the preliminary spraying must be done with a very moderate pressure, and if, even then, the spray does not pass readily through the nostrils, it is better to dilate them by the introduction of cocaine, when no further difficulty of the kind will be experienced. I suspect, however, that the cocaine may to some extent interfere with the therapeutic action of the medicinal agents employed, though it does not, of course, lessen the value of the disinfectants.

In the spraying of the larynx and trachea it is always better to use a very high pressure, and the reasons for this are twofold. In the first place, with the high pressure a very large volume of fluid is introduced in a short space of time, so that in a few seconds an ordinary flask, such as is used in these manipulations, may have its contents half exhausted. And in the second place, the forcible impact against the walls of the mouth and pharynx nebulizes it to such an extent that it is more widely diffused in the respiratory passages. Occasionally a drop of the fluid will form upon the end of the spray tube and fall into the trachea, producing a violent fit of coughing; but, with the high pressure, the time occupied in each introduction of the spray may be so shortened that there is very little danger of this accident.

The advantages to be obtained by this method of treatment over the others to be described later on, are that it occupies very much less time, in consequence of the far larger amount of fluid that can be sprayed into the throat during one or two inhalations, and its better cleansing properties. The forcible introduction of the spray directly into the larynx and trachea gives a much more thorough washing than can be accomplished by the slower methods to be described hereafter.

The treatment of chronic bronchitis by means of the pneumatic cabinet has also been very successful in my hands, as it has in the hands of other gentlemen who have reported their experience with this instrument. The patient is confined in the cabinet under a negative pressure of from two-tenths to five-tenths of an inch. The sitting usually lasts ten minutes, though it may, after the patient has become accustomed to its use, be prolonged to fifteen or twenty minutes. The pneumatic differentiation is accompanied by the inhalation of the spray, for which purpose we employ the "Evans inhaler." The solutions most frequently employed by me are, a twenty per cent. solution of carbolic acid, with borax and glycerine, a solution of the fluid extract of pine needles with iodine, and a combination or mixture of the two solutions in equal parts. When asthmatic breathing is present, the solution of hyoscyamus already referred to is of great value. If much emphysema exists, the cabinet is not indicated. I have never seen any benefit derived from its use in these cases, though I have tried both rarefaction and condensation. The inhalation of the hyoscyamus may relieve the asthmatic breathing, but this may be accomplished just as readily outside the cabinet as in it. In one case a sitting of five minutes in the cabinet developed in a very emphysematous subject, whose breathing was fairly good when he entered the cabinet, a most terrible attack of asthma. The moral effect upon the patient was such that he could never be induced to reënter the box, and promptly transferred himself to the care

of another physician. I have frequently seen it increase the asthmatic breathing temporarily in such subjects, though in others it has produced temporary relief.

The cabinet is particularly valuable in very chronic and intractable cases where the relaxed vessels of the bronchial mucous membrane, though for a time contracted by the action of stimulant applications, soon resume their previous condition of dilatation. The cabinet undoubtedly acts in a twofold manner in these cases: First, as has been pointed out by Dr. Isaac Hull Platt, in a paper read before this Association at its last meeting, by the compression of the bronchial surfaces, and by some alterative effect due, probably, to a combination of the compression with the tonic action upon the vasomotor system of the lungs; secondly, by the action of the spray introduced during treatment. The disadvantage is that, with the spray introduced in this way through the long tube, we do not get the same cleansing effect as can be obtained in the direct method previously described. To obviate this difficulty, I have adopted the practice of first thoroughly cleansing the upper air-passages with the Sass' apparatus before the introduction of the patient into the cabinet.

The apparatus which Dr. George A. Evans introduced to the profession about two years ago has been used in a number of cases with generally satisfactory results. It consists of an ordinary "Wolff" bottle with a glass globe on top, into one side of which is introduced the point of an ordinary spray tube, while from the other emerges a tube for the collection of pulverized spray. It is a modification of the idea of Sales-Giron, and depends upon the principle that when a coarse spray is forcibly thrown against a surface it will be broken up into minute particles and form a fine nebula which will float in the atmosphere several minutes before being precipitated or evaporated. The grosser part of the spray remains in the globe and falls through a tube, back into the "Wolff" bottle, while the more finely nebulized portion is carried off through the tube of exit, from which it is inhaled by the patient. The mouth-piece consists of a hard rubber tube with an opening on one side, the tube held in the mouth of the patient, and the opening on its side covered by his forefinger during inspiration; during expiration the finger is removed so as to allow the breath and spray to pass out through the side opening. The patient is instructed to make deep and slow inspirations, with the idea of securing, as far as possible, voluntary expansion of the chest. The solutions employed have been about the same as those used in the Sass' spray and the pneumatic cabinet.

The advantages claimed by Dr. Evans for his method are that, first, the patient is compelled to make voluntary efforts at deep inspiration during a space of time ranging from half an hour to an hour. By this means a valuable system of pulmonary gymnastics is put into operation. Second, the spray, very finely nebulized, and introduced directly into the air-passages in great volumes, has a better opportunity of diffusing itself in the residual air, and so reaching deeper into the lungs, than it could do under any other circumstances. Third, by means of the fine nebulization much stronger solutions may be employed than with the ordinary coarse spray. For instance, we have frequently employed a thirty per cent. solution of carbolic acid, a strength which could not be tolerated if applied to the air-passages in a liquid form, but which is easily inhaled by any one who is not extraordinarily sensitive.

The first few inhalations of these strong solutions occasion some cough, but this soon passes away, and the patient will continue to inhale for a long time without any further disturbance. At the termination of the sitting, the mouth, pharynx, and larynx, are pretty thoroughly anæsthetized, so that a feeling of numbness exists which lasts for an hour or more. Though the volume of spray as it issues from the tube seems very large, hanging as a cloud in the atmosphere of the room for a long time, still very little of the fluid is used up in its formation, and not enough is carried into the respiratory passages to have ever produced any symptoms of carbolic acid poisoning in the patients upon whom we have used it. As the precipitation of the coarse globules of spray has been thoroughly accomplished before it is introduced into the mouth, no fluid is deposited upon the mucous membranes, but they are simply subject to the mild action of the vapor or spray during the time of the sitting, and the spray itself is all thrown out through the mouth and nose. This method of treatment is particularly useful in cases in which the mucous membranes are extremely sensitive, in those accompanied by violent spasmodic cough, and where the disease is of very long standing, and a prolonged application of the medicinal agent is desirable. Its disadvantage is that, as the spray is introduced by no power except the inspiratory suction, it does not come with sufficient force to the mucous membranes to cleanse them thoroughly. But this objection has been overcome, as in the case of the cabinet patients, by thorough preliminary douching with the spray from the Sass' apparatus. By inhaling through the mouth, and exhaling through the nostrils, medication of the nasal as well as the lower air-passages is obtained.

To get the most satisfactory results by this method it is necessary to employ a high pressure of air. I commonly use a pressure of from fifty to sixty pounds to the square inch. But Dr. Evans, who has a more elaborate apparatus for the compression of air, employs a pressure of seventy to eighty pounds. The advantage consists in the greater volume of spray produced. The inspired air is loaded with it, and during the exhalation it pours from the nostrils in a cloud such as is seen to issue from the nostrils of a horse on a very cold and damp day. Where the membranes are very irritable, and the stronger solutions of carbolic acid are not well borne, a mixture of fluid extract of pine needles with iodine is very serviceable, and, as in the case of the Sass's apparatus, it is frequently combined with an equal portion of a ten or fifteen per cent. solution of carbolic acid. I have also used solutions of tannin with the Evans' inhaler, but the spray is exceedingly disagreeable to the patient, and apt to produce nausea. I have not employed any other astringents with this apparatus.

CHRONIC INTERSTITIAL PNEUMONIA AND BRONCHIECTASIS.

By the local treatment of this affection, three objects are to be accomplished. First, the healing of the bronchial catarrh; second, disinfection of the dilated bronchi: and, third, the restoration of the breathing capacity of such portions of the lung as are not hopelessly degenerated.

The first two objects are best accomplished by the use of the coarse spray or the Evans' inhaler. Each has its advantages, but so far as I am able to judge from my personal experience, the coarse spray is more serviceable.

The third object is to be accomplished through the use of the pneumatic cabinet, or some other apparatus for the inhalation of compressed air.

The method of treatment is first to wash thoroughly and disinfect the nasal and lower respiratory passages with a coarse spray from the Sass' tube. In the treatment of the lower air passages, a high pressure is necessary, so as to give a large volume of spray, and to project it with great force into the respiratory passages. This is at first productive of violent cough, which clears the secretions from the bronchial tubes, after which the spray is deeply inhaled, penetrating, probably, as low as by any other method. After this preliminary washing, the patient is put into the pneumatic cabinet and subjected to a negative pressure of two- or three-tenths of an inch for from fifteen to twenty minutes, while a mild spray is introduced through the tube in order to keep the mucous membrane of the pharynx moist during the treatment. The application of the pneumatic differential pressure in these cases should be made with the greatest care, as there is danger, if the pressure be too great, of producing emphysema of those portions of the diseased lung which are still accessible to air. For this reason, pressures over half an inch should not be employed. The sitting is made rather longer than in the case of chronic bronchitis, because of the necessity for the use of a lower pressure, and with low pressures, as with mild applications of medicinal agents, a more prolonged use is necessary than where the therapeutic agent is of greater power.

By this combined method of treatment, very brilliant results have been achieved in a number of cases which it is not necessary to detail. In some instances, where the cabinet has not been well borne, or where no manifest results were obtained after a fair trial, the Evans inhaler has been substituted for it with very gratifying results. In a few cases no benefit has resulted from any local treatment.

PHTHISIS PULMONALIS.

Aside from the effects of climate, there are no means by which we can obtain so much in the treatment of phthisis pulmonalis as by the use of agents, either physical or chemical, which act directly upon the respiratory organs.

In speaking of these local measures of treatment, I shall confine myself to the three which I have already discussed, namely, the coarse spray, the Evans' inhaler, and pneumatic cabinet. In the selection of a method of treatment for these cases, it is necessary to take account of all the conditions present, because that which benefits one case may be useless or positively injurious in another.

The best results are obtained either in the early stages, when the disease is in its incipient form and no extensive excavation exists, or where the process, though considerably further advanced, is still limited to a comparatively small portion of the lung. The use of sprays is beneficial only in so far as we desire to treat the coincident bronchitis, or where cavities connect with bronchi of the second or third order —*i. e.*, where they are near enough to the trachea to allow of the introduction of a sufficient quantity of the medicinal agent to disinfect them. In deep-seated cavities, and cheesy collections in the smaller bronchi and alveolar spaces, it is questionable whether a sufficient amount of any agent can be introduced through the trachea to have any therapeutic effect. But in large cavities with a free opening into the bronchial tubes, we may, as in the case of bronchiectasis, expect to obtain a certain amount of disinfection. Where naso-pharyngeal catarrhs exist, they should always be treated the same as in chronic bronchitis.

In incipient phthisis accompanied by very little bronchial catarrh, where the cough is accompanied by the expectoration of only a small amount of mucus, local treatment with sprays is of but little avail, and it is not worth our while to spend much time or worry the patient with it. These cases are best treated by the use of compressed air or the pneumatic cabinet, and in a very large proportion of them we may hope to render the disease latent. The action of the positively or relatively compressed air is to expand the lungs, to favor the expectoration of the contents of the smaller tubes and, possibly, of the alveoli, and to modify the intrathoracic circulation, as has been explained by Dr. Platt, and more recently, by Dr. Tiegel in an able article in the *New Yorker Medicinische Presse* for April, 1887.

The sittings should be frequent, every day, or every second day, and the pressure, at first slight, say two-tenths to three tenths of an inch of the barometer, should be gradually increased to one-half or even three quarters of an inch. Ten minutes is usually long enough for each sitting, though in some instances where it is well borne we have prolonged it to twenty and even twenty-five minutes. There is a great difference in the ability of patients to bear the differential pressure. Some experience no difficulty in inhaling under a negative pressure of one-half or three-quarters of an inch for fifteen or twenty minutes, and say that they feel much more benefit from the treatment than when it is lighter, but others soon become fatigued under the pressure of more than one-half an inch, and, on emerging from the cabinet, show signs of great exhaustion. I have met three or four cases in which the pneumatic treatment had to be abandoned because of the exhaustion and thoracic pain following its employment. A safe rule to adopt is never to make the pressure so high, or the sitting so long, that it is followed by a feeling of weariness or exhaustion. Used cautiously in this way it is, I believe, the very best method for the local treatment of incipient phthisis, or of

phthisis limited to a small portion of the apex of one or both lungs. When much bronchial catarrh exists in the earlier stages, the introduction of sprays is all important, and the method is precisely the same as for the treatment of chronic bronchitis. After this preliminary treatment, the pneumatic cabinet is used in the way already described.

So far as the introduction of sprays is concerned, the cabinet is not as useful as either of the other methods; for, while the initial expansion of the lung secured by the operation of compressed air is considerable, the subsequent exhalations do not coincide with it, so that, while the patient is in the cabinet and treated by the diminished pressure, though the chest is expanded and the amount of air actually contained in the lungs increased, this increase is rather in the residual than the tidal air. In some experiments conducted by Dr. Platt and myself, we found that a very robust man could exhale more air after a deep inspiration outside the cabinet than in it. While the expansion of the chest was increased by the action of the compressed air, the expiratory contraction was diminished. Of course, this applies only where the rarefaction is continued during the entire sitting, and would not hold good if the patient were made to inspire under diminished pressure and expire under the normal or increased pressure. But after a number of trials, I have not been able to use the cabinet in this way. Mr. Ketchum, the inventor of the cabinet, tells me that he can operate it in this manner, but possibly, from lack of skill in its manipulation, we have not succeeded in doing so.

With the Evans' inhaler in the treatment of the earlier stages of phthisis, my experience is not so great; as the other methods have proved so satisfactory that I do not generally resort to it. Where it has been used, however, the results have generally been very satisfactory. I believe that its efficacy depends, first upon the effects of the spray on the mucous membrane of the air passages, and, second, upon the salutary influence of the prolonged voluntary attempts at deep inspiration on the part of the patient. Under its use the cough and expectoration are markedly diminished, the patient acquires a gradual expansibility of the chest, and the dyspnœa on exertion is markedly diminished. As the natural result of this, the digestion and appetite improve, the sleep is better, and there is a diminution in fever and increase in weight.

The principles involved in the treatment of more advanced cases differ in no respect from those which we apply in the earlier stages, but certain precautions are to be observed, and less is to be expected in the way of a cure. It is possible, however, in many instances, greatly to improve the general health of the patient by diminishing the expectoration, regulating the pulmonary circulation, and increasing the breathing power. Whether anything can be done in the way of disinfection beyond what we have already alluded to, is very doubtful. It would seem, *a priori*, to be impossible to introduce enough of any antiseptic into the lungs to destroy the caseous foci, disinfect the infiltrated tissues in the neighborhood of the avenues of entrance, and leave enough to prevent a reformation of bacilli during the intervals between sittings. To my mind, the only way in which the progress of the tubercular invasion can be arrested is by so improving the nutrition of the tissues of the lung as to render them immune to the disease. We know that in the case of tuberculosis, as of other infectious and septic diseases, it is only a certain proportion of those who are exposed to the infection who contract the malady. Not every patient who is operated upon under circumstances which expose him to septic infection contracts pyæmia or septicæmia, and antiseptic surgery is for the benefit of those who are vulnerable. It need not be applied in every case if we had the means of knowing which were susceptible and which were not. So, in the case of tuberculosis, it is only those whose tissues are susceptible to the disease who contract it. And when the disease is present, in the absence of any means for thoroughly destroying the bacilli which already inhabit the lungs, our only resource is to endeavor to render the remainder of the pulmonary tissue invulnerable to their attacks.

In the treatment of advanced cases our first aim should be to cure the bronchitis, or so to diminish it as to lessen greatly the expectoration and the cough. This being done, the pneumatic treatment should be carefully applied, in order to get a better expansion and improved circulation, and an alteration of the action of the trophic nerves. The coarse spray, of course, accomplishes but one of these subjects, while the pneumatic cabinet and the Evans' inhaler act in both ways. If the cabinet is used, the patient should first be treated locally with the coarse spray, and, after thorough cleansing, the entire respiratory tract should be subjected to a moderate negative pressure, with the introduction of some unirritating spray.

After the employment of a number of different formulæ, it has seemed to me and my two colleagues, Dr. I. H. Platt and Dr. A. H. Buckmaster, that as good results were obtained by the use of a simple alkaline and carbolized solution, as with any of the others; though, in some instances where great irritability is present, a pine needle extract or the fluid extract of hyoscyamus has done better. We used, for some time, a solution of the bichloride of mercury in the strength of 1 to 1000, but it was not as pleasant to the patient as were the others mentioned, and there was no apparent difference in their therapeutic effects, or, if any, it was in favor of the other solutions. Many other formulæ have been used and advised by other observers, but the active principles of all are similar, and as those that we had used acted satisfactorily, it was not thought worth while to multiply them, as no opinion of any value could be formed in regard to the efficacy of any one agent, unless it were used for a long time and in a large number of cases.

Though the effects of the cabinet have been very satisfactory in cases which were not too far advanced, I think that, on the whole, we have been better pleased with the Evans inhaler. This apparatus has the advantage of being very easily employed. It does not alarm the patient, nor does it fatigue him as much as the cabinet. Of course, if the patient is

very ambitious, and exerts himself to inspire as deeply as possible for a long time, he may soon become exhausted. But when the cases are well advanced, and the patients greatly debilitated by disease, we do not at first urge them to make any great effort at expansion, but simply allow them to hold the tube in the mouth and breathe comfortably. As they become accustomed to its use, they inhale more deeply, the respiratory muscles are gradually strengthened by exercise, and they may finally become able to make a very effective use of the instrument. We have not employed the local treatment alone in any cases of advanced phthisis with extensive destruction of the lung, hectic fever, and copious night-sweats, but have always felt obliged to use other internal medication; so that it is impossible to say, in any given case, to what extent the improvement which has occurred is due to any one of the means employed, but it would appear that the use of these local measures is a valuable addition to our ordinary therapeutic resources.

It is particularly important, in using the pneumatic cabinet on this class of patients, not to make the pressure too high, as it appears from our observation that, where portions of the lung are contracting, no matter how strong a pressure is used, the contraction is not overcome, and any dilatation of the chest which is accomplished is at the expense of the non-infiltrated portions. In one instance the contraction of the lung, which was only apparent above the third rib on the left side at the beginning of treatment, extended, in spite of the daily application of the cabinet, so that, after the lapse of six weeks, it had progressed below the nipple and the anterior border had so far retracted that the cardiac pulsations could be felt over the entire precordial region, from the second intercostal space to the apex. Where this contraction goes on in spite of the judicious use of the cabinet, we may conclude that the instrument is doing no good, and it is as well to resort to other methods of treatment.

We have been somewhat surprised to see tabulated in some of the reports on the use of the pneumatic cabinet, cases of acute phthisis in which cures had been effected. It has been our experience that the more acute the disease, the more rapid its onset, the higher the fever, and the greater and more progressive the emaciation, the less can be accomplished, not only by this, but by any other method of treatment. Indeed, we are unable to report any case which we have diagnosticated as acute phthisis, on which local treatment has had any effect whatever. The patients are generally very weak, feverish, and irritable, and the application of these local measures simply exhausts them.

I would say, in closing, that the success of the local treatment is largely dependent upon the constitutional condition of the patient. Some, who appeared to have a very trifling amount of local disease have gone down very rapidly in spite of all that we could do. This has been particularly observed in alcoholic subjects. In one instance, that of a man twenty-eight years old, engaged in the retail liquor business, whose pulmonary difficulty was limited to the upper half of one upper lobe, and consisted largely of solidification without much apparent excavation, and where good results were confidently expected, treatment was found to be very exhausting, and, in spite of the greatest care, the patient rapidly declined. I have been told by Dr. Jacob Fuhs, through whose courtesy we had the opportunity of seeing him, that he subsequently developed a myelitis followed by paraplegia and rapid dissolution. On the other hand, there have been cases where the disease seemed very far advanced, and extended over a considerable portion of both lungs, which have done well from the start, sometimes very much to our surprise. The difference is undoubtedly dependent upon the constitutional resistance of the patient, and we desire particularly to call attention to this fact, in order to illustrate the principle that it is not well either to abandon any case because of its apparently desperate nature, or to base too hopeful a prognosis upon the slight extent of the local lesion.

174 CHRISTIAN STREET, BROOKLYN, N. Y.

CYCLIC ALBUMINURIA.[1]

BY WILLIAM BUCKINGHAM CANFIELD, M.D.,
CHIEF OF THROAT AND CHEST CLINIC AND LECTURER ON NORMAL HISTOLOGY, UNIVERSITY OF MARYLAND; MEDICAL EXAMINER FOR THE MANHATTAN LIFE INSURANCE COMPANY.

THE interest and importance of this subject are the only excuse that can be offered for bringing such a hackneyed theme before the Academy. The presence or absence of albumen in the urine has been and probably always will be a matter of more or less grave importance to the practitioner, whether in examining for life insurance or in other practice. So-called "physiological albuminuria" had been suspected for some time by early investigators, but not until recently have decided views been expressed.

Sir William Gull,[2] in 1873, and Dr. Moxon,[3] in 1878, called attention to the frequent occurrence of albuminuria in youths and young persons. In these cases, however, it was temporary, passing off after a short time. Leube[4] and Fürbringer[5] made more extensive investigations which were of decided value. Leube examined the urine of 119 soldiers and found albumen in the morning urine of 5, and (after a march) in the afternoon urine of 19, and no albumen at night; about 4 per cent. had albuminous urine in the morning, and 12 per cent. in the afternoon. In no case was the amount of albumen over 0.1 per cent., and there was also no sign of blood, neither hæmaturia nor hæmoglobinuria, nor of casts, and only occasionally uric acid crystals present. The specific gravity was always between 1.013 and 1.022. Fürbringer examined the urine of 61 children and found albumen in 7 cases, or about 11 per cent. Others have found passing albuminuria after a cold bath or active muscular exercise. Mahomed[6] found in 77 persons who came up within 12 months for life insurance examination, albumen in 12 cases,

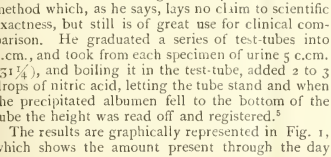
or 15.5 per cent. These cases were only examined once and in the forenoon. He feels confident that we can have albuminuria with healthy kidneys, although he lays, and with justice too, great stress upon the necessity of examining the condition of the vascular system.

Pavy[1] was probably the first to describe the cyclic character of this albuminuria. He noticed that the condition of one day was repeated with more or less exactness the next. V. Noorden[2] and Bull,[3] of Christiania, also report similar cases.

In Leyden's clinic in Berlin, a young man, a student, was found to have albumen in his urine. An assistant, Dr. Klemperer,[4] suspecting cyclic albuminuria, examined the urine day after day, taking specimens from eight different hours in the day. The patient passed his water at 6.30, 7.30, 8.30, and 11 A.M., and 2, 6, 10, and 11 P.M., taking care to empty the bladder entirely each time. The examination extended over a period of three months, and as the urine was tested under different circumstances and as the student was a very willing subject, the results are interesting. Klemperer followed a method which, as he says, lays no claim to scientific exactness, but still is of great use for clinical comparison. He graduated a series of test-tubes into c.cm., and took from each specimen of urine 5 c.cm. ($5\frac{1}{4}$), and boiling it in the test-tube, added 2 to 3 drops of nitric acid, letting the tube stand and when the precipitated albumen fell to the bottom of the tube the height was read off and registered.[5]

The results are graphically represented in Fig. 1, which shows the amount present through the day

FIG. 1.



when the student followed his daily avocation in the ordinary routine of lectures, meals, exercise. He generally awoke at 6, arose at 7.30 and drank a cup of coffee, and at 11 took breakfast. In the morning he was either at home or attending lectures. At 1 P.M. he took dinner, at 4 he drank coffee and at 8.30 supper. He generally took a walk between 4 and 6 P.M., and usually remained at home in the evening. The urine which he passed on waking was free from albumen; that passed on dressing and undressing (7 30 A.M. and 11 P.M.) contained the most. From 11 A.M. to 6 P.M. he passed the least. There seems to be a fall in the morning and a rise in the evening.

When he remained in bed one hour longer than usual the urine passed at 7.30 A.M. was free from albumen, while that passed at 8.30 contained the most. On one occasion he remained in bed until noon, and then the morning urine was entirely free from albumen, and even at 2 P.M. there was only a trace, showing the influence of rest on the albumen.

Again, after he had spent the morning working as usual, he went to bed at 12 noon, and, except for a trace of albumen observed at 6 P.M., the afternoon urine was entirely free. At several different times he remained in bed the whole day, and in every instance the urine was found to be entirely free from albumen. Finally, he spent one entire day in working especially industriously at his books, not going out to lectures nor for exercise, and the albumen was present in his urine all day with a maximum at 11 P.M., thus showing the influence of mental exercise.

Nothing else pathological was found in the urine, which was in every case clear, transparent, acid, with a specific gravity of 1.005 to 1.020. The daily amount passed was 1500 to 1800 c.cm. (40 to 50 ounces). All sediment, even oxalate of lime, was absent. No sugar was present. He spent the summer in Switzerland, and the next winter returned to Berlin, having gained in weight. Examination of the urine showed a less amount of albumen which, however, still retained its cyclic manner of appearance.

While under observation the patient varied his diet, some days taking milk alone and again only meat, and all without any influence upon the amount of albumen. As an invariable consequence of resting the urine was always free from albumen.

The following case recently came under my care. F. H., aged thirty two, stout, little color, married. He does not complain of being unwell, although his position as druggist keeps him very much confined, from 7 A.M. to 12 midnight. He gave no history of gout, rheumatism, nephritis, or syphilis, but had had intermittent fever. Examination of the heart and radial pulse showed nothing abnormal. He saw very well. He applied about eighteen months to two years ago for admittance to a life insurance company, and was much surprised to find that he was rejected on account of albumen in his urine. He was told he would die in a few months, and was naturally much frightened, although at the time he felt very well and had a good appetite. He consulted many physicians, and took different things, changing his diet with each physician, and examining his urine himself very carefully, as he had abundant opportunity of doing. He noticed, as time went on, no great change; now there would be less albumen, now more, and occasionally none. In one of these happy, non-albuminuric intervals he again applied for life insurance, but unfortunately for him, by the time the examiner reached him albumen had again appeared in his urine.

He gradually became accustomed to his position,

[4] Klemperer: Archiv f. klin. Med., Bd. xii.
[5] To estimate approximately the amount of albumen present, we may say that when 2 to 3 per cent. of albumen is present, the whole fluid is coagulated; 1 per cent., the coagulum reaches one half way up; 0.5 per cent., one-third way up; 0.1 per cent., one-tenth way up; 0.05 per cent., barely fills the curved part of the test-tube; when less than 0.01 per cent., there is a slight cloudiness but no precipitate.

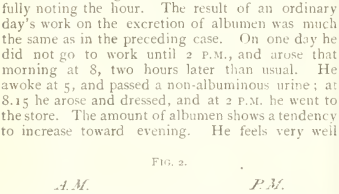
and now seems to be thriving under it, having gained in weight since last year. I have examined his urine at different times and under different circumstances in the past few months, and have rarely failed to find albumen. For the sake of comparison I have followed the method employed by Klemperer, not, however, neglecting to test the urine with other reagents.

The amount passed per day was about thirty to forty ounces in cold weather; it was acid at every test, and the specific gravity (taken at every test) ranged between 1.019 and 1.031. Examination of the sediment microscopically showed only oxalate of lime and uric acid crystals, and no casts. He also informed me that none of his attending physicians had ever found casts. The specific gravity reached 1.030 and 1.031 on a few occasions, and then the albumen was most abundant.

In using the layer test of Heller I was occasionally struck with the intense color of the ring of urates above the acid, and have since had my attention called to a statement of Dr. Sedgwick Saunders, who, in making tests for Ralfe,[1] noticed that on the days when the albumen was most abundant, the specific gravity was above the normal, whilst the ring of urates which formed just above the cold nitric acid on which the urine was floated, when the albumen was most abundant, was always intensely colored by the oxidized pigment of the urine.

Unfortunately I was unable to get specimens of urine at stated hours from my patient, as Dr. Klemperer did from his, still I found him ever ready to assist me in saving the urine in bottles, and in carefully noting the hour. The result of an ordinary day's work on the excretion of albumen was much the same as in the preceding case. On one day he did not go to work until 2 P.M., and arose that morning at 8, two hours later than usual. He awoke at 5, and passed a non-albuminous urine; at 8.15 he arose and dressed, and at 2 P.M. he went to the store. The amount of albumen shows a tendency to increase toward evening. He feels very well

FIG. 2.



Shows the average daily amount of albumen passed for each hour.

and cheerful, and his only desire is to have his life insured.

Without going into the pathology of this disease, it is evident that rest and work play an important part in its etiology. The most generally accepted theory is that some change in the epithelium covering the glomerular vessels allows the albumen to pass through into the urine—a condition which the normal epithelium prevents. An extended and careful observation can alone give a decided diagnosis. I have used the heat test, the nitric acid test, nitric acid and heat, picric acid, and the nitric-magnesian test of Roberts, and I think that no one should be satisfied with a single test.

As for the prognosis, Leube, Fürbringer, Moxon, and Mahomed would no doubt be in favor of insuring persons with cyclic albuminuria, while Johnson,[1] and others, hesitate, and seem to think that such cases probably end in some form of nephritis. Dr. Munn,[2] as Medical Director of the United States Life Insurance Company of New York, finding that nearly ten per cent. of all deaths of policy-holders in his company occurred from some form of Bright's disease, made an extensive examination of the urine of all applicants from 1877 to 1880. He used the heat and nitric acid test, holding the test-tube containing the urine before a reflected light. He lays great stress upon the care with which the urine should be examined—*i.e.*, acidified, if alkaline, and allowed to stand a sufficient length of time after the addition of the acid. In following up the histories of the rejected cases, he found, in 1880, that four had died out of sixty-nine, and the general health of those who had been under observation for more than one year was gradually deteriorating, and for this reason he was inclined to regard albuminuria as of grave significance.

Without attempting to draw any inference from these cases, I think one or two points deserve notice. When a urinary examination is to be made, the applicant for life insurance should bring specimens passed in the forenoon and afternoon as well as at night. If albumen be present, a sufficient number of examinations should be made before a diagnosis between a nephritis and cyclic albuminuria be made. In every case a microscopic examination should be made, as casts may be present when albumen is absent. Of course, so called accidental albuminuria, due to gonorrhoeal pus, or to some inflammation in the ureters or bladder, should not be mistaken for Bright's disease.

Treatment seems to have little or no influence upon this form of albuminuria. Ralfe seems to think that time alone, and not drugs, will cure it. Saundby,[3] also, admits that he could never cure one of these cases. My patient is at present taking iron in the form of the tincture of the chloride, but at the time the above test was made all medicine was purposely withheld.

WAKING NUMBNESS.

BY C. L. DODGE, M.D.,
OF KINGSTON, N. Y.

THE MEDICAL NEWS, of June 4, 1887, called attention, editorially, to an article by Dr. Andrew H. Smith, of New York, in the April number of *The*

[1] George Johnson: British Medical Journal, 1870. II.
[2] John Munn: Medical Investigations in Life Insurance.
[3] Saundby: British Medical Journal, November 27, 1886.

American Journal of the Medical Sciences, where he describes a curious neurosis characterized by numbness on waking, either general or confined to the distribution of the ulnar nerves. I wish to add two cases to Dr. Smith's collection, as this certainly is a very rare affection.

Case I.—Twenty years ago, a lady, thirty-eight years of age, consulted my preceptor for a peculiar numbness and tingling sensation in the left arm, extending to the tips of the little finger and the ulnar side of the ring finger. She was quite alarmed about it, and imagined it was commencing paralysis or something of that kind. She herself attributed it to overwork and a strain of the back. She was advised rest, friction, and tonics, and she improved, but has been subject to these night attacks (they never occur at any other time) ever since, though free from them for weeks at a time.

The most singular circumstance about the second case is that the gentleman affected in this peculiar way is a son of the lady mentioned above.

Case II.—A gentleman in good health, thirty-three years of age, actively engaged in professional work, has, for over twelve years, experienced these same numb, tingling sensations, *occasionally* on waking out of a sound sleep; in his case the sensation exactly resembled that which results from pressure upon a nerve, and which we commonly speak of as the foot being asleep. Motion, sensation, and the tactile sense were entirely unaffected, although the arm felt heavy and dead, as he expressed it. It sometimes happens on one side and then on the other, but he is positive that it is not caused by pressure upon the nerves. The peculiar sensation does not last over a minute and never recurs again the same night. He also told me that it once happened to him some years ago, in the daytime, when he fell asleep in a chair, and at that time he was in such a position that no pressure could have been made upon the nerves. In his case the numbness never extends above the shoulder and rarely above the elbow. It appears to commence in the extremities of the fingers and extend up the arm.

Dr. Smith says, "from a study of these cases it is apparent that the numbness is something added to the normal condition, while nothing is subtracted from it. It is a purely subjective condition. Doubtless the conditions upon which the numbness depends are present during sleep, but the sensation is not sufficiently strong to arouse the sleeper, and he first becomes conscious of it when awakened by some other cause." The cause of this condition Dr. Smith thinks, is probably central, since the effect is usually symmetrical. One of his cases, however, and both of mine, were affected in one arm only.

I am inclined to think that sexual excesses bear a causative relation to this condition. At least, in Case II. the gentleman admitted that he thought he experienced the sensation more frequently when given to excesses of this kind.

As to treatment, I advised him to take more outdoor exercise, to be temperate in all things, and apply friction to the parts. I also prescribed tonics to improve the general health.

MEDICAL PROGRESS.

Artificial Foods for Infant Feeding.—Dr. Edgar Everhart, Chemist to the University of Texas, reported as follows to the State Scientific Association, on the analysis of the foods most commonly sold for infants:

1. No infant food, as now sold, can be made up, either with or without the addition of cow's milk, so as to produce a liquid having as great an amount of total solids (13.75 per cent.) as are in woman's milk, unless indeed such total solids consist of such an injurious substance as starch, or the casein of cow's milk.

2. Not one of these infant foods is composed of nitrogenous matter that is as easy of digestion as is that of woman's milk. The chief source of such nitrogenous matter is cow's milk, and not the foods themselves. The fact that starchy matter prevents the formation of clots in cow's milk, is no reason for introducing a still more indigestible substance in a child's stomach than would be the clots themselves. Besides, the formation of a clot is not the only reason of the greater indigestibility of casein.

3. The percentage of fat is uniformly too low for the requirements of the infant organism.

4. Because the soluble carbohydrates, even when present in large amounts, are different in chemical properties, and most likely also in physiological, from the milk sugar contained in woman's milk.

5. Chiefly because the great majority of infant foods introduce a substance into the stomach of the child which is never found in woman's milk, and which we know by direct proof cannot be assimilated by the digestive system of an infant.

6. In those cases where there is an approximation to woman's milk, this approximation is due to the use of cow's milk. The use of such foods as Liebig's is not so objectionable as the farinaceous; they are only useless, because their only function practically is to increase the percentage of the carbohydrates. This increase can be as well and more cheaply made by the addition of a little ordinary sugar, or, still better, by milk sugar. The addition of Liebig's food does not change the character of the nitrogenous matter of cow's milk, either before or after it is taken into the stomach.

Colored Gauze as used in Lister's Wards.—Dr. Senn writes of a visit to Lister's wards as follows: "The only thing that was new to me in the way of dressing wounds was the colored gauze, which is used to distinguish it from gauze not rendered aseptic. Great importance is placed upon the disappearance of color on the surface of the gauze, as an indication that the secretions from the wound have reached the surface, an occurrence which is looked upon as a necessity for a change of dressing. A number of lumbar abscesses were shown which had been simply incised and drained, and where the whole dressing was composed of a very thin and small compress of gauze and a layer of absorbent cotton still smaller than the gauze compress."—*Journal American Medical Association*, June 4, 1887.

When Can Diphtheria be Diagnosticated?—Simon, of Paris, in an article in *Le Progrès Médicale*, of June 4, 1887, writes as follows: "Supposing that your

first visit has been made in the morning, return the same evening; and if you can define a small whitish pellicle which, beginning at the first point in the throat which was affected, has spread until, like a spider's web, it is about to attach itself to the opposite side of the throat, and if, above all, the *velum palati* is implicated, do not hesitate to affirm that diphtheria is present."

Hydrochloric Acid and Laudanum for Cholera Infantum.—Henoch has used successfully the following:

Sweetened water . . .	a teaspoonful.
Laudanum (Sydenham's) .	½ to 2 drops.
Dilute hydrochloric acid .	2 drops.

This dose may be repeated several times daily, as indicated.—*Revue Générale de Clinique*, June 23, 1887.

An Application for Freckles.—

Fresh milk	ʒ 12½.
Glycerine	ʒ 7½.
Acid. hydrochloric. dil. . . .	♏ 75.
Hydrochlorate of ammonia . .	ʒ 1.

Dissolve.

Touch the freckles with a brush dipped in the solution morning and evening.—*Journal de Médecine*, June 5, 1887.

The Treatment of "Heat-stroke" in the English Army.—Surgeon G. Douglass Hunter describes the following treatment which he used successfully among the English troops in the tropics:

Treatment must be immediate and thorough. The patient should be stripped and laid in the coolest place possible—in the shade outside is best—and cold water dashed on the head and spine; this should be maintained; a large enema administered, and the lower bowel well emptied. If the patient regains consciousness, he may then be placed on his bed (if the temperature remains high) in a wet pack, and ice kept to his head. Five grains of calomel may then be administered, and diaphoretics given frequently. To promote free action of the skin and maintain the action of the bowels is very needful. If a relapse threatens, douching should be at once resorted to. If there are no signs of rallying, use sinapisms to the heart, frequent douching, ice to head and spine, friction of the limbs; if the pulse is failing, brandy at frequent intervals in small doses and brandy enemata. If respiration is failing, artificial respiration should be employed and well kept up. On no account give up every attempt until life is quite extinct. On no account bleed the patient. The after-treatment is to maintain free action of the skin and bowels—tonics and change of air to a temperate climate.

The essence of treatment is to reduce the bodily temperature as speedily as possible, and the surest way to do this is by the application of cold water and ice; this should be maintained, and the least relapse dealt vigorously with in the same way. Immediate action of the bowels by enemata is very necessary, and an emetic is beneficial in suitable cases.—*British Medical Journal*, July 9, 1887.

A New Hypnotic.—At the recent meeting of the Society of Neurologists and Alienists of Southwestern Germany, held at Strassburg, von Mering reported his use of amylen-hydrat, or tertiary-amyl-alcohol, in 60 cases. The drug was administered 250 times to patients suffering from mental and nervous disorders. Its dose ranges from 30 to 75 minims; sleep so produced lasted from six to eight hours, and no ill after-effects followed. Its taste is more agreeable than that of paraldehyde. It was given in the following mixture, which was well shaken before taken:

Amylen hydrat.	ʒ 1.
Aq. dest.	ʒ 10.
Ext. liquritiæ	ʒ 1.

—*Deutsche medicinische Wochenschrift*, June 23, 1887.

Treatment of Perihepatic Tubercular Abscess.—Lannelongue, in a paper read recently before the Academy of Sciences at Paris, recommended

1. Simple incision and thorough disinfection and drainage of such abscesses when readily accessible.

2. The resection of the lower ribs to the sixth or seventh whenever necessary to secure free access in treating abscesses upon the convexity of the liver, hepatic abscesses proper, and hydatid cysts subdiaphragmatic.—*Gazette Hebdomadaire*, June 10, 1887.

Asthma Therapeutics.—Lazarus, of Berlin, is quoted as follows by the *Journal of Laryngology* for May, 1887:

1. The prophylaxis of bronchial asthma requires a report of the hereditary and constitutional conditions present, and especially of the condition of the mucous membrane of the nose and throat.

2. The asthmatic attack must be suppressed as soon as possible. The best medicament for this purpose is iodide of potassium and chloral. In special cases operative treatment of the nose and naso-pharynx is recommended.

3. The treatment of the secondary affections is the more important in that they may become causes of recurrence of the asthma. For these conditions the best treatment is the pneumatic chamber. In chronic catarrhal conditions of the bronchi the best treatment is turpentine and iodide of potassium.

Tuberculous Contagion Conveyed by the Meat of Fowls.—Lamallerée recently reported to the Paris Academy of Sciences a case where a phthisical husband conveyed tubercular contagion to his wife, who, after his death, developed pulmonary tuberculosis. She sold fowls to a neighbor, with whom she had no other association. The flesh of these fowls was eaten underdone, and the neighbor, after consuming eleven of these chickens, showed tubercular pulmonary disease.

Examination of a fowl showed the presence of tubercle and bacilli. The expectoration of the owner of the chickens had been profuse, and the fowls had eaten the sputa.—*Semaine Médicale*.

A Convenient Formula for Oil of Wintergreen.—Much difficulty has been reported in finding an eligible mixture containing oil of wintergreen, so

valuable in acute rheumatism, and also employed in other affections. The following may be commended:

℞.—Olei gaultheriæ . . . . . ♏clx.
Mucilag. acaciæ . . . . . f℥ij.
Glycerinæ,
Aquæ . . . . . ää f℥j.
M.—Sig. Dose, one to two teaspoonfuls, as may be required.—*Pharmaceutical Record*, June 15, 1887.

BARIUM CHLORIDE IN VASCULAR DISEASES.—KOBERT, of Dorpat, Russia, writes as follows in the *Therapeutic Gazette* of June 15, 1887: The best application for dilated cutaneous veins (for example, on the legs) is the following:

℞.—Barii chloridi . . . . . gr. xxx.
Dissolve in distilled water and mix thoroughly
Lanolini . . . . . ℥ij ¾.
Olei amygdalarum dulc. . . . ♏lxxv. M.
F. Unguentum.
Sig.—Three times daily, with friction, whenever dilated blue veins shine through the skin.

Barium chloride can also be used hypodermatically in place of substances of the digitalis group, in cases of heart-disease where help is demanded so soon that remedies given internally are not available.

THE ODORS OF INFECTIOUS DISEASES.—DR. NIVEN writes as follows on this point, in an article on fevers in the *Medical Chronicle* for June, 1887:

It is a fact of some interest, at all events from a diagnostic point of view, that some of the infectious diseases possess special odors. The only odor, besides that of rheumatic fever, I have seen any mention of in literature is that of typhus fever, which is of a peculiarly heavy and offensive nature, and has been likened to the smell of rotten straw. It is quite characteristic, and is obviously not the result of filth, since it is present in the cleanliest people who have contracted the disease. It is evidently some special product of the virus of the disease, or of the tissues under its influence.

It is doubtful whether the same thing can be said of the disgusting and peculiar odor of smallpox, which occurs only in the worst cases, and is of the gravest omen. It is not present in cases which do well, even where the body is covered with scabs, and it therefore probably means merely necrosis of the tissues, and a ptomaïne generated in that process.

Some six years ago I made a minute study of scarlet fever, and I was very much struck by a peculiar sweet odor of the breath, almost aromatic in character, which, though far from unpleasant in itself, is rendered unpleasant by its associations. I also observed that this odor is most marked in the early stages of the disease. That this is no mere imagination will be clear when I mention that a nurse to whom I pointed this out, diagnosticated the occurrence of scarlet fever in a smallpox patient at the height of the smallpox, a whole day before any other symptoms of scarlet fever appeared, simply from the peculiar scarlatinal odor of the breath, and I have myself on several occasions been able to diagnosticate scarlet fever in this way before the appearance of the rash. This smell is sometimes excessively strong, especially in cases of what I should call toxic scarlet fever, where the throat is but little affected, the rash is discrete and dark, and there is much delirium. It is then like a powerful and heavy ether.

The same peculiar and sweet odor is fairly often to be observed in the breath in cases of typhoid fever, but never attains the penetrating and powerful character that it does in certain cases of scarlet fever. I have not been able to distinguish between the odors of typhoid and scarlet fever.

Measles also has a smell of its own, somewhat resembling that of scarlet fever, but quite distinguishable.

THE TREATMENT OF LARYNGEAL PHTHISIS.—MASSEI, of Naples, reports the results of his study and practice in laryngeal phthisis as follows:

1. We are still in want of some remedy, or remedies, to effect the cure of laryngeal phthisis.

2. Notwithstanding this want, the local (palliative) treatment of the disease is incumbent upon every physician.

3. Many of the cases quoted by various writers are of an extremely hypothetical nature, inasmuch as they have not been a sufficient time under observation.

4. Cocaine, iodoform, iodol, and sublimate are perhaps the best of all local remedies. Lactic acid, even by submucous injection, does not appear to have led to favorable results.—*Journal of Laryngology*, May, 1887.

CORROSIVE SUBLIMATE AND UREA IN SYPHILIS.—SCHUTZ has employed the following formula:

Aquæ destillat. . . . . ℥ 3½.
Hydrarg. bichlorid. . . . . gr. 15.
Ureæ . . . . . gr. 3½.

The amount of urea may be increased to eight grains. Fifteen minims daily should be given by hypodermatic injection. Twenty-six cases have recovered under this treatment, which acts more easily, promptly, and with less pain than do injections of other combinations.—*Journal de Médecine*, June 5, 1887.

FIFTEEN OPERATIONS UPON THE PREGNANT UTERUS.—HOFMEIER, of Schröder's Clinic, in Berlin, reported fifteen operations at the recent German Surgical Congress, whose results were as follows: Seven were cases of pregnancy complicated by carcinoma uteri, for which five supravaginal and two total extirpations were done; there were six cases of fibroma, and two Cæsarean sections. The mortality was two—one after supravaginal, and one after total uterine extirpation. Four cases were followed by abortion and return of the original lesion; and for one of these, in a woman the second time pregnant, a total extirpation was done. Fibromata were removed from the uterus twice—once at the end of pregnancy, once at five months. No difficulty was experienced in operating. After the elastic hæmostatic bandage was applied, the uterine wound was closed by étage sutures, and the peritoneum was carefully stitched over the incision with catgut. No hemorrhage came from a stump so sutured; it was replaced in the abdomen.—*Berliner klinische Wochenschrift*, May 30, 1887.

BACTERIA IN INTESTINAL DISEASE.—ESCHERICH, of Munich, in an exhaustive article in the *Centralblatt für Bacteriologie*, No. 24, concludes as follows:

Our knowledge of intestinal bacteria has made little

advance because of our ignorance of the bacteria found in normal intestines, and our lack of differentiation as to pathogenic and non-pathogenic bacteria.

Our efforts are at present confined to attempts to sterilize food, and we have as yet few researches upon the nature of intestinal bacilli themselves. The line of progress lies in this direction, and it is more than probable that analysis will separate cholera infantum into several diseases closely allied in nature and causation.

A SUCCESSFUL CASE OF EXTIRPATION OF THE LARYNX.—At a recent meeting of the French Society of Otology and Laryngology FAUVEL exhibited a patient, on whom Péan had, in 1885, performed extirpation of the larynx, leaving only the epiglottis and part of the arytenoid cartilages. The patient had resumed his occupation; he succeeded in making himself understood in a feeble, guttural sound, but in words formed by the mouth and lips; this voice, deficient in quality, was audible at a moderate distance. No appliance to improve his voice had been successful. The diagnosis before operation lay between epithelioma and syphilis.—*Revue de Largyngologie*, June, 1887.

A FORMULA FOR THE USE OF HYOSCINE AS A HYPNOTIC.—DR. DORSET, of the State Insane Asylum of Texas, has found the following of benefit:

Hyoscine hydrobromate	$\frac{1}{100}$ gr.
Paraldehyde,	
Oil of almonds	āā ʒ 2.
Chloroform	♏ 10.
Oil of cinnamon	♏ 2.—M.

The medicine given at bed-time, in drachm doses, in a great number of cases, is all that is necessary to secure a quiet, refreshing night's rest. The patients are not so nervous the next morning, and are ready to take a good breakfast.—*Texas Courier Record*, June, 1887.

THE TREATMENT OF PULMONARY PHTHISIS BY LARD WITH MILK.—DR. N. AKIMENKO, of Professor V. G. Lashkevitch's clinic, in Kharkov, writes that, having many a time heard of excellent services obtained by the Russian peasantry from treating various wasting chest diseases by the internal use of lard with milk, he resolved at last to give a fair trial to that popular remedy in several cases of early pulmonary phthisis. In all the cases the affection was diagnosticated on the ground of Koch's microbe being present in the patient's sputa. The method was practised in the following way: he took the fat from the omentum and mesenterium of a recently killed pig, soaked it for twenty-four hours in cold water, then picked out all connective tissue, and boiled from a quarter to a third of a pound of the fat with three glassfuls of unskimmed milk on a slow fire, for three or four hours, until about two glassfuls of fluid were obtained. The latter was then strained through a piece of muslin, and cooled down to be administered (after duly shaking) to the patient, the dose being at first one quarter or half a glassful three times a day; but by the end of a second week as many as three glassfuls a day. The results obtained were these: (1) The patients' weight invariably increased (in one of the cases the patient gained nine and a half pounds in thirty-three days). (2) Cough and expectoration were alleviated, while the quantity of sputum considerably lessened. (3) The appetite always improved. Such patients in whom the loss of appetite had formerly amounted to a complete aversion from meat, after the treatment of two or three weeks' duration, requested me to allow them an additional meat-dish. (4) The patients took the lard emulsions with pleasure; no digestive disturbances were ever observed. Pointing to his results, Dr. Akimenko recommends his professional brethren to try the lard treatment in phthisis, especially in such cases where cod-liver oil cannot be employed on account of its "verily disgusting taste," or in consequence of its causing gastric disturbances.—*Provincial Medical Journal*, June 1, 1887.

A STIMULANT INHALATION.—

R.—Essenc. terebinth.	ʒ 3ss.
Picis Norwegiensis	ʒ 5.
Chloroformi	♏ 15.—M.

Sig. By inhalation, to relieve hoarseness.—*Journal de Médecine*, May 15, 1887.

WHAT SALT OF QUINIA SHALL BE USED HYPODERMATICALLY?—*The Therapeutic Gazette*, of May 16, 1887, answers this question as follows:

As regards *quinine*, the question appears to be settled, for the time being at least, in favor of the *hydrochlorate*. At the last meeting of the Paris Society of Pharmacy (April 6th) the merits of the rival claimants, the sulphovinate and the lactate, were discussed and summarily disposed of. The *sulphovinate* has the disadvantage of decomposing when kept, and thereby becoming apt to cause abscesses when injected; the *lactate* of being but little soluble when crystallized, so that the solutions have to be made extemporaneously from freshly precipitated quinine and lactic acid, with some precautions to insure the percentage of active principle. On the contrary, the hydrochlorate is a stable compound, sufficiently soluble, and easily procured from dealers in well-defined crystals, much less liable to adulteration than the ordinary medicinal sulphate. The reason of this comparative purity may be that the sulphate is an old acquaintance of the dealers, in fact, too familiar to them, while the hydrochlorate is a new-comer. But it is unnecessary to borrow trouble; suffice it to say for the present that this salt appears to be the most eligible quinine compound for hypodermatic uses, and that it is, in the actual state of science, found in commerce unadulterated with other cinchona alkaloids.

MENTHOL AND COFFEE FOR CORYZA.—

R.—Menthol. pulv.	gr. 3.
Coffee roasted and finally ground,	
Pulverized sugar	āa gr. 75.

Use as a snuff.—*L'Union Médicale*, June 9, 1886.

TWO CASES OF INTRACRANIAL TUMORS.—At the recent meeting of the Fourth Congress of Italian Surgeons CECCHERELLI reported a case of sarcoma of the dura mater, whose site was the border of the right frontal eminence; another situated at the border of the right parietal eminence. The first case recovered; the second died.—*Revue Générale de Clinique et de Therapeutique*, No. 10.

THE TREATMENT OF PHTHISIS.

IT must be admitted by those who deny the paramount etiological importance of the tubercle bacillus, that its discovery has given a much-needed impetus to the treatment of pulmonary phthisis. In proof of this statement, it is only necessary to point to the unusual number of papers upon this subject that have recently been read before the principal medical societies in this country and in Europe. One of the latest and most interesting of these discussions, in which DETTWEILER and PENZOLDT were referee and co-referee, took place at the Sixth German Medical Congress, recently held at Wiesbaden.

Although the question is not formally discussed, it is apparent that the first of these authorities is not prepared to deny the predisposing influence of constitutional and local processes, while the latter virtually announces his adherence to the doctrine of predisposition when he speaks of those who are vulnerable either through heredity or acquired disposition.

The referee and co-referee and those who followed them in the discussion, viz., BREHMER, MESS, THIEME, and HAUPT are practically of one mind with reference to treatment. The greatest importance is attached to a life in the open air, preferably in a region that is known to possess an immunity from phthisis. With reference to this latter point, the geological formation, as well as the atmospheric conditions of a health resort, must be considered. According to Gauster, the greatest immunity from phthisis exists in regions composed of mica schist, gneiss, and granite; the least in those where these so-called primary rocks are mingled with dolomite and chalky formations in general.

The open air cure—*dauerluftkur*, as it is significantly called in German—is not contraindicated by the greatest prostration, for patients unable to walk may be carried out of doors in their beds or in reclining chairs.

Fever is the worst enemy of the consumptive, and is to be combated by absolute rest in bed in the open air, with as liberal a diet as can be digested. Alcohol is advised to the extent of one-half to three-fourths of a pint of light red or white wine per diem, to be taken at meals, and, in cases which require it, from two to three ounces of cognac between meals. The new antithermal agents, antipyrin, thallin, and antifebrin, may be employed with benefit. Sweating may be controlled by the timely administration of an alcoholic stimulant, by atropine, agaricine, and, in the opinion of the writer, most effectively by picrotoxine.

When the fever is subdued, and not till then, muscular exercise, at first consisting of systematic movements in bed, and later, if the strength increases, of short walks with frequent rests, is to be taken daily.

This open air system is, so to speak, a hardening one, and to this hardening process Dettweiler attaches the greatest importance, for it affords the patient a greater immunity against the danger of repeated catarrhs of the air-passages. These catarrhs (colds) are peculiarly prone, in the phthisical, to invade the smaller bronchi, in the secretions (catarrhal) of which the bacilli, if inhaled from a higher focus, are detained and multiply in fresh colonies. Dettweiler urgently recommends the prompt and energetic treatment of every fresh catarrhal attack. His method is to place the patient in bed, with sufficient covering to induce rapid perspiration. He is then vigorously rubbed and supplied with change of clothing.

When all is told, the fate of the phthisical depends upon his ability to partake of and digest a sufficient amount of proper food, and it is an unfortunate anomaly of the disease that physiological hunger is in inverse ratio to the actual needs of the tissues for nourishment. At least one quart of milk should be taken in the interval between meals, to which may be added, if milk is distasteful, a small quantity of cognac, *kirschwasser*, carbonic acid water, or a little cold coffee or tea.

With reference to drugs, Penzoldt enters more into detail than does Dettweiler. He regards morphia as indispensable, but says nothing with reference to its dose or time of administration. It is a valuable palliative, and should not be administered an hour longer than the conditions are present for which it was indicated. These are general malaise, pain, and restlessness. As a hypnotic it is inferior to chloral. Inhalations of turpentine and tannin

may be used with advantage to check profuse expectoration. In the treatment of hæmoptysis, rest, ice, and morphia are considered more efficacious than styptics.

Thieme, of Mentone, was the only one of those who took part in the discussion who reported results from the treatment by gaseous enemata. He stated that while the accepted cause of the disease, the bacillus, was not removed, the general condition of the patient was improved by this method.

In this connection reference may be made to the discussion of Fräntzel's paper in the *Verein für innere Medicin*, at the meeting of May 16, 1887, on the use of creasote in the treatment of pulmonary tuberculosis. Experiments have shown this substance to be inimical to the growth of the bacillus when mingled, in minute quantity, with a gelatine culture medium, and on this fact is based its internal administration. The reports concerning the results of treatment by this drug are variable, but in a certain number of cases in the early stage it appears to be beneficial. Great importance is attached by Lublinski and Fräntzel to the use of a pure preparation from beech-wood.

By common consent a hygienic treatment, such as that outlined in the foregoing presentation of the views of Dettweiler and Penzoldt, is the most efficacious, and this will continue to be the case in the event of the discovery of the much hoped-for specific; for, supposing the local disease brought to a standstill by the removal of its cause, by no other means can the enfeebled system be roused to the labor of the retrograde ascent to health.

SUPPURATIVE PUERPERAL PERITONITIS.

Besnier recently reported to the Paris Society of Medicine a case which is typical of a class not infrequent, and very little amenable to medical treatment.

A young and previously healthy woman had completed her third normal labor under the care of a midwife. On the fourth day after confinement she was attacked by acute septicæmia, which she withstood with the aid of change of air, tonics, and stimulants. Besnier saw her six weeks after delivery: her abdomen was distended by an encysted abscess. Emaciation, malaise, apyrexia, night sweats, and a rapid, feeble pulse completed the picture of septicæmia. The pus-cavity was punctured and five and a half quarts of pus were evacuated. The cavity promptly refilled, but the patient's general condition was much improved, and she began to assimilate food and stimulants. The after-treatment consisted in the application of tincture of iodine and collodion to the entire abdomen, and the free use of tonics. The fluid and membrane which had lined the pus-sac were gradually absorbed, and cure followed in six weeks.

Beginning septic peritonitis after operations has been cured, in a few cases, by prompt disinfection and drainage. Rose, Tait, Mikulicz, Krönlein, and others, have operated for diffuse peritonitis with a few successes. Diffuse suppurative peritonitis is a disease whose mortality is very high. When of tuberculous origin, it may be greatly benefited by drainage; but the character and relative positions of the abdominal contents are such that a diffuse septic process offers the greatest difficulty to operative treatment.

In the case under discussion the first indications of sepsis should have been met by prompt intra-uterine disinfection, of which the midwife was ignorant. Under the existing circumstances, one of two procedures was admissible: ventrotomy with exploration and disinfection of the cavity, and aspiration with the injection of iodoform in ether or vaseline. The choice rested upon the diagnosis of encysted, and not diffused, suppuration.

In the present case the suppurative process was thought to have been "benign," probably because recovery followed. This doctrine, although venerable, is a poor rule of action; and the patient's cure must be ascribed more to the resistant powers of the peritoneum, and the patient's ability to assimilate food and tonics than to any benignity on the part of the ptomaines and bacteria of septicæmia.

The occurrence of diffuse septic peritonitis is one of the most serious complications of parturition, and is to be met by the prompt application of those principles of conservative surgery which are so successful in like conditions elsewhere in the body.

EXCISION OF THE MEMBRANA TYMPANI AND THE OSSICLES OF HEARING.

Since the time of Valsalva it has been known that loss of the membrana tympani and the ossicles, except the foot-plate of the stapes, does not cause complete deafness, but at most hardness of hearing. Nevertheless, an erroneous impression has gained a hold in the minds of physicians and the laity, that loss of the membrana tympani necessitates loss of hearing. The first endeavors to excise the membrana partially, with the view of aiding the hearing, date from the beginning of this century, and were made by Karl Himly and Sir Astley Cooper. Similar trials were made by Deleau, Fabrizi, and Brunner (1841), and by Bonnafont as late as 1860. But their instruments and their operations were clumsy and rough, and their results very unsatisfactory. Their aim was to make and maintain an opening in the membrana, rather than to excise either it or the ossicula. But they all alike failed to make a permanent opening. Wreden then pro-

posed to resect part of the handle of the hammer, hoping thus to prevent entire healing of the opening in the membrana. But this method failed in its object, as all previous ones had done. This was especially disappointing, as in most cases the hearing improved so long as the opening in the membrana was maintained.

Then came a variety of suggestions as to ways of making a permanent opening in the drum-membrane, as, for example, by means of iodide of mercury, sulphuric acid, and the galvano-cautery. But the opening thus made would always close as soon as all the acute symptoms of inflammation had subsided. The operation for making a permanent opening in the drum, in order to improve the hearing, was then given up. The fact that in purulent processes the hammer and the incus can be thrown off without a very high degree of hardness of hearing as a result, led to the idea that obstructions in the sound-conducting parts of the tympanic cavity, lying to the outward of the stapes, and caused chiefly by immobility of the hammer and anvil, could be removed by excision of the ossicles.

Schwartze performed excision of the membrana, and extraction of the entire hammer, for relief of sclerosis, in 1873. The temporary improvement in hearing disappeared as soon as the imperfectly excised membrane had formed again. Lucæ, of Berlin, seems to have performed a similar operation in a number of cases, but his results are not fully published. Kessel, of Prague, has suggested that to prevent a regrowth of the membrana tympani, the annulus cartilagineus, in the posterior circumference of the membrana, be removed, and eventually a resection of a portion of the sulcus tympanicus be performed by means of a chisel.

In 1886, DR. SAMUEL SEXTON, of New York, presented a paper before the American Otological Society, in which he set forth "A New Operation for the Radical Cure of Chronic Purulent Inflammation of the Middle Ear Tract." In this procedure the remnants of the membrana tympani, and especially that part of it known as the membrana flaccida, are first cut away, and then the malleus and the incus are removed, the latter being first separated from its attachment to the stapes. This operation has been performed by Dr. Sexton nineteen times within the past year and a quarter, with very satisfactory results as to the cure of the chronic otorrhœa, and improvement in hearing in many cases, although the operation was not undertaken for the attainment of the latter result.

As the operation is of importance, the foregoing historical sketch seems demanded, in justice both to the profession and the laity, in order that both may see the legitimate development of a valuable surgical operation.

SPONTANEOUS RUPTURE OF THE CORD.

RUPTURE of the umbilical cord in labor is a comparatively rare accident. It has occasionally occurred when a woman has been surprised by the expulsion of the child while she was standing, the child falling to the floor, for a sudden force less than the weight of the child will cause the cord to give way.

But can there be a spontaneous rupture if the woman be delivered in bed? This is a very important question in medical jurisprudence. For example, if a mother be found with a recently born child that is dead, the death having been caused by bleeding from a ruptured cord, that rupture occurring at the umbilicus, or at some other part, one might hastily conclude that the injury was done by the mother, or by some one else, and its purpose was to kill the child. Some cases, however, reported by BUDIN, in the *Annales d' Hygiène Publique* for June, 1887, prove that the conclusion might be quite unjust; in other words, spontaneous rupture of the cord may occur where there has been no interference whatever, and the mother was delivered in bed. The number of cases of this accident presented by Budin is four, the first by Schatz, the second by Dupuy, and the other two occurred in his own service in La Charité. In neither of Budin's cases was there any relative or absolute shortness of the cord, and it was of usual size; the rupture occurred solely from the utero-abdominal contractions which expelled the child.

MOUNT HOLLY, N. J., is suffering from an epidemic of typhoid fever, which is said to have originated in the water supply becoming polluted by the fecal discharges from a case of typhoid fever which existed during the spring at Smithville, a small village about four miles above the town and on the creek from which the water supply of Mount Holly is drawn.

It is well nigh impossible to prevent the pollution of water courses, but ample experience has shown that it is easy and an imperative duty to disinfect typhoid stools before emptying them, and thus to destroy their power of propagating the fever.

THE twentieth annual meeting of the West Virginia State Medical Society was held at the White Sulphur Springs, on July 13th, 14th, and 15th, under the presidency of Dr. Samuel L. Jepson, of Wheeling. A number of distinguished members of the profession from neighboring States were present and contributed to the proceedings. Dr. Luther S. Brock, of Morgantown, was elected president for the ensuing year, and Huntington was selected as the next place of meeting.

THE State Board of Health of West Virginia has attained an enviable reputation by reason of its efficiency and the professional standing of its members. On the accession of the present Governor, the influence of the administration appeared to be against the work of the Board. Bills incurred by the Board were refused approval, appointments provided by the State laws were neglected, and, finally, a member, said to be ineligible under the laws of the State, was appointed to office.

This appointment led to a protest by twenty-nine physicians of Wheeling; the State Medical Association, at its late meeting, denounced the action of the Governor, and public sentiment is in accord with that of the profession in resenting it.

Nothing is more deplorable than the refusal of the State to coöperate with and support the efforts of the medical profession for the public good.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-th Annual Meeting, held July 10, 1887, at New London, Conn.

Specially reported for THE MEDICAL NEWS

MORNING SESSION.

The Society was called to order at 10.30 A. M. by THE PRESIDENT, DR. J. S. PROUT, of Brooklyn.

PRELIMINARY BUSINESS.

DR. E. E. HOLT, of Portland, was elected Secretary *pro t m.*

Resolutions expressing regret at the absence of THE SECRETARY, DR. J. J. B. VERMYNE, who was prevented by ill health from being present, were adopted, and the Secretary of the meeting was directed to forward a copy to Dr. Vermyne.

The report of the Committee of Conference with reference to the formation of a

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was adopted, and the following resolution was also adopted:

Resolved, That the Society expresses its acquiescence in the general plan for the formation of a congress of special societies, as set forth in the printed minutes of the Washington meeting of September 24th. The naming of the representative and alternate to executive committee of the congress was left to the nominating committee.

DR. H. KNAPP, of New York, presented

THE EXAMINATION OF THE POWER OF HEARING, AND HOW TO RECORD ITS RESULTS,

the report of a committee consisting of Drs. H. Knapp, J. S. Prout, and D. B. St. John Roosa. The tests for hearing described were the watch, the voice, Politzer's acumeter, and the tuning-fork. The watch is one of the best means of testing the hearing. A low-ticking watch is of service in indicating the lowest degree of hardness of hearing in those cases where the patient has not become aware of the defect. This is, however, not sufficient to measure the higher degrees of deafness. In these cases a loud-ticking watch or Politzer's acumeter must supply its place. Each of these instruments must be tested by the physician in his office on a number of normal ears, in order that he may obtain a standard. It is a fact that in persons over fifty-five years of age, a low-ticking watch may not be heard when placed over the temporal or mastoid bone if the ear is closed, but will be heard if the ear is open.

With reference to the voice as tests for hearing, the whispered voice, the voice of ordinary conversation, and the loud voice, are used. Each observer must test his own voice by the acuteness of hearing of normal persons between the ages of twenty and forty-eight years of age. The state of the room as to noise and quiet should always be considered.

The tuning-fork over all parts of the skull is heard louder and longer when the ear is closed than when it is open. All tuning-forks are heard longer by air-conduction than by bone-conduction. Low tuning-forks are heard louder, but not longer, by bone-conduction than by air-conduction. Departure from these conditions indicates disease.

DR. SAMUEL SEXTON, of New York, thought that sufficient importance had not been given to the varying conditions of the patients themselves. He found that in cases of chronic catarrhal inflammation of the middle ear, and also in acute forms of inflammation, that there are constantly varying changes in the tension of the drum and in the transmitting mechanism. In these cases the acuteness of hearing changes from hour to hour or day to day. He had noticed that in the morning, when the perceptive faculties are active, a patient will hear better than he will later in the day. It is also well known that the vapor tension of the air, as well as the temperature, has something to do with the transmission of sound. The hearing is better in cold weather than in hot. He thought that there would always be difficulty in obtaining accurate tests for the more interesting cases which come under observation.

DR. ST. JOHN ROOSA, of New York, was not inclined to lay such stress as has been done on the variations in hearing from hour to hour in cases of chronic inflammation of the middle ear. These variations do occur in cases of disease of the middle ear, but he thought that they are more marked in disease of the internal ear. In cases of nervous deafness the condition of nervous exhaustion has much to do with the capacity for hearing.

DR. SAMUEL THEOBALD, of Baltimore, mentioned an observation bearing upon the use of the tuning-fork, which he had made in a number of instances, and which he had been unable to explain. In certain cases, when the tuning-fork is placed on the vertex, the patient will hear it louder in one ear, say the right; then striking the fork again, and placing it upon the forehead, it will be heard best in the left ear. This had given him less confidence in the tuning-fork as a differential test between middle-ear and labyrinthian troubles.

DR. KNAPP said that for practical purposes we must test the hearing as accurately and with as little loss of time as possible. In certain cases of chronic catarrh we get no change in the hearing power by any test. In these cases, he thought that nothing is to be looked for from treatment. Where, however, by changes of weather, or changes in the patient's condition, there is a change in the hearing power, we know that there is

something to improve. We get not only an estimation of the condition, but we also get a foundation for prognosis and an indication for treatment.

DR. CHARLES H. BURNETT, of Philadelphia, reported a case of

SUCCESSFUL REMOVAL OF AN EXOSTOSIS FROM THE EXTERNAL AUDITORY CANAL BY BONE-FORCEPS AND CHISEL.

The patient was a physician, about thirty years of age, in whose right ear the exostosis had been growing for fifteen years, and within the past year it had entirely occluded the meatus and caused deafness. The growth was about one centimetre in diameter, pediculated, and attached to the anterior wall of the meatus just within the outer edge of the tympanic bone. Its outer surface was covered with thick and rather insensible skin. After a hypodermatic injection into the concha of fifteen minims of a five per cent. solution of hydrochlorate of cocaine, the outer surface of the exostosis was seized by specially devised bone-forceps and a piece of the bone tumor cut off. About one-half of the growth was thus removed in successive pieces. As the blades of the forceps could not enter further into the meatus and get hold of the remnant of the exostosis, a small chisel a few millimetres in width was placed against the attachment, and a blow from a hammer on the chisel knocked off the remainder of the growth *en masse*. The operation caused very little pain or bleeding. The fundus of the canal and the membrana tympani were covered with a glove-finger cast of epithelium. This was removed, and the hearing found to be normal. The ear was dressed with a little iodoform and stopped with cotton. There was no reaction, and the cut surface of bone on the wall of the meatus at the point of attachment of the exostosis, was entirely covered with skin in two or three days. Usually drills impelled by the dental lathe have been used to open the lumen of the canal occluded by exostosis. The novelty in this case consisted in the use of bone-forceps, devised by the author to remove the growth as far as possible, and then the use of hammer and chisel to complete the opening.

DR. KNAPP said that to attack exostoses at the apex with the chisel, where they consist of ivory bone, is most difficult. The most efficient way in his experience is to attack them at the base. Here the bone may be much softer. In the after-treatment cleanliness and antiseptic precautions are of the utmost importance. He considered this a safe and the most efficient method of removing these ivory tumors with large bases.

DR. J. A. ANDREWS, of New York, endorsed what Dr. Knapp had stated. Where these osteomata are situated in the orbit, much serious injury may be inflicted upon the brain by the use of the chisel. It would be much easier to fracture the plate of bone lying against the brain in osteoma of the frontal sinus by attacking the tumor itself than by attacking the bony surroundings of the growth.

DR. D. B. ST. JOHN ROOSA read a paper on

THE DIFFERENTIAL DIAGNOSIS BETWEEN AFFECTIONS OF THE MIDDLE EAR AND THOSE OF THE LABYRINTH.

There has been some difference of opinion as to our ability to differentiate between affections of the middle ear and those of the labyrinth. Many cases usually classed under affections of the tympanum should be placed among diseases of the cochlea or of the acoustic nerve. The records of seven recent cases were given in detail. These cases were nearly all in the middle period of life, when its cares and troubles are most pronounced. Such patients often exhibit symptoms of nervous exhaustion. These cases may be benefited by the administration of strychnia, arsenic, and quinine. Proper hygiene should be employed. The universal use of the watch as a test of hearing occasionally leads to false conclusions on the part of the general practitioner, who discovers loss of hearing by testing with the watch alone. When used alone, I regard the watch as inefficient. When both the watch and the voice are heard badly there is cause for anxiety. Many persons have lesions which cause them to hear the watch and certain other tones badly who can hear the voice well. In the opinion of the author, those persons who hear conversation better than the watch, who hear better in a quiet room than where there is noise, and who hear the tuning-fork better through the air than through the bone, suffer from an affection of the labyrinth or nerve, and not from disease of the tympanum, although the latter may be engrafted upon the previous affection. The general adoption of this view would save a good deal of local treatment of the nasopharynx and tympanum, and greatly simplify and improve our therapeutics.

DR. EMIL GRUENING, of New York, asked if the cases described by Dr. Roosa were benefited by general treatment?

DR. ROOSA said that, as far as the aural condition is concerned, he regarded these cases as incurable. He thought that we could assure those patients that if the general health be looked after carefully that they will never hear so badly but that they can hear in a quiet place. This has a good moral effect. It makes the patient happier, and enables us to dispense with such useless treatment.

DR. HOLT for several years had performed experiments with the tuning-fork, but had not been able to reach the conclusions presented by Dr. Roosa. We may find quite a degree of deafness, and still the tuning-fork will be heard longer by air conduction than by the bone. He had seen many cases where bone conduction would be longer than air conduction, and where by treatment the air conduction would become longer. It is difficult to test the hearing properly with the watch, unless it is made with a stop. In his own case, he hears the watch very badly. He hears the tuning-fork by air conduction three or four times longer than by bone conduction. In an ordinarily quiet room he can hear all that is said, but in the cars he can hear better than a person with normal ears.

DR. ROOSA said that the case of Dr. Holt would not agree with his experience, which is that a person who hears well in a quiet room, and who hears the watch badly, always hears worse in the cars than he does in a quiet room.

DR. ROOSA then made some

REMARKS UPON A CASE OF CEREBRAL ABSCESS.

The patient, a boy, aged eleven years, came under observation May 4, 1887, with a painful swelling over the right ear. It was said that the boy had had some

trouble with the ear two years before, but that there had been no discharge. For three months he had tinnitus aurium and vertigo. One week before he was seen he had pain in the ear, then this swelling appeared. Bone conduction with the tuning-fork was better than aërial conduction. The hearing of the left ear was normal. Immediately above and in front of the auricle there was a swelling the size of a walnut. This presented fluctuation. There was a history that previous to admission to the hospital the treatment had consisted in the use of injections and the insufflation of powders. The auditory canal was filled with a white substance, which was supposed to be the powder that had been employed. The day after admission the patient was etherized, and the abscess opened with the removal of half an ounce of laudable pus. No fistula was discovered. The patient did well for nine days. Nausea and vomiting then set in, and the temperature went up to 104°. The patient sank into a condition of coma, and died on the tenth day after admission. At the autopsy there was found a cerebral abscess one and one-half inches in diameter, situated in the temporo-sphenoidal lobe, one-half inch from the surface of the brain. This was lined with thick membrane. The membrana tympani was perforated, and the upper wall of the canal was necrotic. At the junction of the mastoid and squamous bones, there was a spot of necrosis one-half inch in diameter. The canal and mastoid cells were filled with caseous material.

DR. ROOSA also reported the history of a case of

SUPPURATION OF THE TYMPANUM OCCURRING IN A PATIENT WITH BRIGHT'S DISEASE.

The patient, a woman, aged forty-two years, was seen April 11, 1887. There was intense pain referred to the left ear, which had existed since the day before. The hearing was much impaired as the result of a chronic non-suppurative inflammation of the middle ear. The bone conduction was better than the aërial. There was a watery discharge from the left auditory canal. Examination of the urine revealed the presence of Bright's disease, and the patient died some days later from œdema of the lungs. The point which the author made was that although this patient complained a good deal of the mastoid proces, it was determined that there was no lesion requiring operation, because of the absence of the characteristic symptom of tenderness at the apex. The case was regarded as one of tympanic trouble. The post-mortem proved that there was no trouble with the mastoid, but acute suppuration of the tympanum occurring in a patient with chronic non-suppurative inflammation. The patient died with Bright's disease.

DR. W. H. CARMALT, of New Haven, remarked that the author spoke of tenderness of the mastoid as though it were an almost infallible sign of suppuration in the mastoid cells. He asked if we should expect to find this sign always?

DR. ROOSA thought that this is a very strong test, although by no means infallible.

DR. GRUENING last winter saw a number of cases of abscess. In children he opens the abscess, and invariably opens the mastoid cells, especially where the abscess has been preceded by otitis media purulenta. In four of the seven cases the mastoid cells were filled with pus. In this way, thorough drainage was established, and all the patients recovered. He saw three cases of otitis media purulenta treated by insufflation of powder, leading to retention of secretion and death. All died of meningitis.

DR. B. E. FRYER, of Kansas City, asked whether the abscess and the affection of the ear were of the same duration?

DR. ROOSA thought that the cerebral abscess was of long duration, months, possibly years. The abscess was undoubtedly induced by the tympanic disease.

DR. LUCIEN HOWE, of Buffalo, remarked that this case called to mind one which he had seen in a child where there was a history of recurring attacks of ear trouble with discharge. It was stated that good results had been obtained by the use of alum and boric acid. This was continued and the patient began to develop the typical signs of mastoid trouble. He etherized the child and removed the accumulation in the outer ear and all the symptoms then subsided.

DR. W. H. CARMALT said that the fact that the cerebral abscess was surrounded by a thick membrane did not prove that it was of long duration. In a recent case of cerebral abscess resulting from an injury over the parietal bone, he attempted to reach the abscess by trephining, and passed a knife two and a half inches in the direction where he supposed the abscess to be, but got no pus. The man died, and an abscess was found in about the position exposed. The wall was so thick that the pressure of the knife had squeezed the pus into the lateral ventricles and death had been the result. In this case the operation was performed within two months of the original injury.

DR. E. E. HOLT, of Portland, read a paper on

AN EFFICIENT POWDER BLOWER, WITH REMARKS ON THE USE OF POWDERS IN THE TREATMENT OF DISEASES OF THE EAR.

The powder blower consists of six or eight inches of small glass tubing to which are attached about fifteen inches of rubber tubing. The glass tube is plunged into the powder until a sufficient amount is introduced into it. The powder is gently drawn into the proximal end of the glass tube. The distal extremity is then placed in the speculum and the powder blown into the ear. By drawing the powder from the distal end before blowing it, it is carried *en masse* to the desired point and applied evenly to all parts. The instrument can be used with great facility. After trying various powders, boric acid has been found the most efficient in the largest number of cases. One of the first cases in which the author had used this powder was one in which treatment for over two years had failed to cure a suppurative otitis media. Upon the application of the powdered boric acid the discharge ceased, and has not returned, a period of five years. Cleanliness, before using the powder, is essential. A comparison of cases of chronic suppurative otitis media treated with boric acid with those treated without this agent, led to the conclusion, that while the discharge from the ear ceases much earlier when the powder is used, yet perforations in the drum head heal less frequently.

DR. SAMUEL THEOBALD exhibited a powder blower similar to that of Dr. Holt, with the exception that the glass tube was substituted by a piece of goose-quill and

that the rubber tube was furnished with a mouth-piece consisting of a quill. The powder is introduced into the quill and by shaking brought to the proximal extremity of the tube, the object being that it shall be thrown into the ear in the form of a cloud.

Dr. Wm. W. Seely, of Cincinnati, had never seen any benefit from blowing powders into the ear. He had seen only good results where the powder is packed into the canal. He, however, now rarely uses the powder in any way. In these cases of suppuration there are three points to be observed: the Eustachian tube should be kept open, the naso-pharynx should be treated as in any other case of inflammation of the middle ear, and the ear should be kept clean by the use of cotton probes.

Dr. Roosa, of New York, had found the syringe the best means of cleaning the ear. He uses powders with great circumspection, and considers them inferior to other methods of treatment.

Dr. B. Alexander Randall, of Philadelphia, said that in treating a number of cases of purulent discharge which had continued from five to fifteen years, and in which the discharge had been pretty continuous and fetid, he had cleansed the canal and used boric acid; at first blowing it in lightly, and finally filling the canal pretty full without packing. Within a few days the powder is dissolved, and the discharge is usually diminished in quantity and the odor is lost. In eight out of every ten cases, that had been his experience. He had never seen any bad results.

Dr. Knapp used boracic acid in acute cases of otorrhœa as an antiseptic and cleansing powder. The patient is directed to cleanse the ear with the syringe three times a day. The powder is then introduced by means of a spoon until the canal is loosely filled. If the powder becomes moist the patient is directed to syringe the ear and renew the application. The majority of acute cases do not require any other treatment. In chronic cases he removes any polypoid growths or any carious bone that may be present, and then uses alcohol in fifty or sixty per cent. strength or absolute with sulpho-carbolate of zinc, and changes that with nitrate of silver. He continues this treatment until the ear is dry and there is no discharge, and then directs the patient to do nothing beyond using a light cotton plug to filter the air. He does nothing to the perforations. In one case he makes an exception, and that is when a perforation of moderate size has perfectly clear edges and remains in the same condition for weeks or months. Here he pastes a small piece of sized paper over the perforation. In many cases the hearing is improved, and it seems to stimulate the healing of the perforation.

Dr. C. R. Agnew said that in using fluid applications in the treatment of these cases he had employed a procedure which might be new to some of the members. After cleaning the ear in which he wants to diffuse a fluid application as much as possible, he turns that ear uppermost and fills the external canal with the solution. Then he inserts the nozzle of the Politzer apparatus into the external canal and makes pressure, diffusing the liquid to all parts of the ear and making it appear in some cases in the pharynx. This sometimes may be of value.

Dr. Samuel Theobald thought that both powders and solutions may be used with advantage. He had never seen any direct harm follow the use of boracic acid. In cases of suppuration, with a small or moderate sized perforation, he had seen it dry up the discharge and leave the perforation larger than before its use. In such cases he prefers solutions. In acute cases his practice is always to use solutions. He had used a fifteen grain solution with satisfaction. Where the drum-membrane is practically gone, with a granular condition of the mucous membrane the use of boracic acid powder is indicated. He had never found it necessary to pack the canal. One puff of the powder-blower fills the canal sufficiently full.

Dr. Knapp said that in acute suppurative otitis, which is certainly of bacterial origin, he used boric acid largely on account of its drying properties. Suppuration, fermentation, and decomposition do not take place where a part is kept dry. The ear is unfavorable for thorough drainage. As soon as the boric acid becomes moist he has it removed. For acute cases he knew nothing better than this method of treatment.

Dr. Emil Gruening made a few remarks with reference to three cases which he had already mentioned. In these cases he attributed the fatal result to the use of powder, which was boracic acid. The first case, that of a girl, nineteen years of age, had otitis as a result of the use of the nasal douche. She was advised to use powders. In a few days she began to suffer with headache, dizziness, and intense tenderness on one side of the head and slight puffiness in the region of the mastoid. The author saw the patient after she had become comatose. The tympanic membrane was bulging and injected; there was a slight tit-like projection, and in this there was an opening filled with powder. The pus which formed in the middle ear escaped through the Eustachian tube. He made an opening in the membrane and cleaned it out carefully, and advised the family physician to open the mastoid. He did so, and found the mastoid cells filled with pus. The patient recovered consciousness, but died the next day from heart failure. The second case was that of a lady, seventy years of age, who had otitis media with perforation. A powder was applied by a general practitioner, and a few hours later she began to suffer with intense headache. Symptoms of meningitis appeared. There was a small opening in the membrane occluded with powder, an opening was made, but the patient died of meningitis. The third case was that of a child with long standing otitis media, and destruction of both membranes. This is the only case in which the powder had been packed. After the ears had been packed the child had repeated chills. The speaker was called in and removed the plugs, which were hard, concrete masses, and were taken away with difficulty. In spite of the removal of the powder the child died with all the symptoms of pyæmia.

Dr. Roosa thought that in a large percentage of cases acute inflammation of the middle ear is a self-limited affection. He tried to secure cleanliness and then dry the parts. He does not use dryness as a means of destroying the germs or preventing them from acting, for he does not believe in the germ theory of disease. He considers that germs are the products and not the causes of disease, and thinks that they retard the recovery and therefore should be removed. In a large proportion of the acute cases the only treatment required is irrigation with warm water *pro re nata* and drying afterward. He

believes that the pus has a chemical quality apart from the presence of germs, which renders it corrosive. He therefore tried to keep the parts as free from pus as possible.

DR. S. SEXTON thought that it would help in the discussion to consider the kind of cases in which boric acid is useful. Where there is a catarrhal inflammation of the atrium there is generally a profuse discharge which renders it difficult to apply the powder. In the cases referred to by Dr. Gruening, where there is a nipple-like formation, there is little discharge from the atrium. In these cases he makes an early and free opening, and in this way has avoided many of the consequences which are apt to follow in these cases. He makes this opening with a stout tenotome. An opening is made through the membrana flaccida into the attic and through the integument of the upper wall, which usually becomes tumefied.

DR. S. THEOBALD desired to enter a protest against the view that the good effects of boric acid are due entirely to its drying qualities. Some of his most brilliant results have been with the solution of boric acid. He has had cases in which the discharge stopped after a single application of a saturated solution of boric acid.

DR. J. A. LIPPINCOTT, of Pittsburg, considered boric acid a most valuable agent and would not care to relinquish its use. There are, however, certain cases in which, as a result of idiosyncrasy on the part of the patient, the powder acts as an irritant. In the cases reported by Dr. Gruening the fatal results are to be attributed to its improper use. It seemed to him that the dangers of boric acid can be avoided by applying it in the form of a loose powder.

(To be concluded.)

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-third Annual Meeting, held at New London, Conn., July 20 and 21, 1887.

Specially reported for THE MEDICAL NEWS

WEDNESDAY, JULY 20TH—FIRST DAY.

OBITUARY NOTICES.

DR. DERBY, of Boston, read a sketch of the life of the late Dr. Ezra Dyer, of Newport, R. I., formerly of Philadelphia, one of the founders of the Society, and DR. H. D. NOYES briefly referred to the character and work of the late Dr. Wm. S. Little, of Philadelphia.

SIMPLE EXTRACTION OF CATARACT WITHOUT IRIDECTOMY.

DR. C. S. BULL, of New York, reported thirty-six cases of extraction by Daviel's method. The age of the patients ranged from thirteen to seventy-nine years. Of the cataracts 24 were hard, 11 soft, and 1 of traumatic origin. Strict antiseptic precautions were taken both as to operation and after-treatment. Solutions of bichloride of mercury were used for washing the operator's hands and the patient's face, of the strength of 1 : 1000, while a solution of 1 : 500 was repeatedly used to wash out the conjunctiva, and the instruments were left lying in an alcohol bath. The corneal flap was cut with a narrow Graefe knife, and included two-fifths of the circumference of the cornea. Usually the iris did not prolapse. The capsule was then opened with a cystotome, and the lens extracted by manipulation. The iris, if it had prolapsed, was then replaced. Any lens matter remaining in the anterior chamber was washed out by a solution of the bichloride 1 : 10,000; eserine was then instilled into the anterior chamber; the eye covered with sterilized linen and absorbent cotton and bandaged. The bandage was not removed for two days; but the bichloride solution and instillations of eserine were introduced beneath it twice a day. If the eye seemed to be doing well it was not opened until the fourth day, when the bandage was removed for the second time, then replaced and kept on one day longer. The patient was carefully confined to bed, and this was regarded as very important. In 20 cases the iris had to be reduced, but no case of secondary prolapse occurred, and none of suppuration. In the first 30 cases there had been no incarceration of the iris, but this had occurred near the periphery in the last 6. Plastic iritis occurred in 6 cases, irido-choroiditis in 2, in 2 the corneal epithelium was lost some days after the operation, but subsequently regenerated. The average duration of treatment was twenty days. Two required subsequent needling, one the excision of a piece of capsule.

In 20, a central pupil was secured; in 16, pupil displaced. Vision of $\frac{20}{XXX}$ to $\frac{20}{C}$ in 33 cases, of $\frac{20}{CC}$ in 2 cases was obtained. The remaining case had light perception.

This operation preserves the natural appearance of the iris. Central vision is about the same as after the ordinary extraction with iridectomy, and peripheral vision better. There is less liability to the incarceration of the capsule in the wound. But the technique of the operation is much more difficult. This plan of operation is contraindicated by a narrow anterior chamber, fluid vitreous, or rigid iris; and an iridectomy must be made if the corneal incision is too short, or the iris falls before the knife while making it.

PERIPHERIC-LINEAR EXTRACTION WITHOUT IRIDECTOMY.

DR. H. KNAPP, of New York, had made sixty-eight such cataract extractions, beside eight cases in which the operation was attempted but an iridectomy had to be made. The after complications and accidents were mild iritis 3 cases, severe iritis with closure of the pupil 1, protrusion of the iris 3, incarceration 1, capsule-iritis 1, and suppuration 1. The remainder did well. Vision was entirely lost in one case, and was less than $\frac{10}{CC}$ in two other cases. The pupillary area is obstructed by wrinkled capsule quite as frequently as after other extraction operations. In one case prolapse of the iris occurred on the fourth day; in attempting to excise it the prolapse was partially reduced, the reduction was completed, and the eye recovered with a perfectly central pupil. In the case of a man addicted to excessive drinking the eye recovered well with $V. = \frac{20}{L}$. Later, a needle operation was done, and twenty-four hours afterward the patient was attacked with dysentery and acute nephritis. Circumcorneal injection and chemosis appeared, and the eye got very hard. By the third day movements of the hand were alone perceived. An iridectomy was done which cured the eye. On the whole, this method of cataract extraction seems as safe, and on

some accounts preferable to the ordinary method with iridectomy.

ONE THOUSAND SUCCESSIVE CASES OF CATARACT EXTRACTION.

DR. H. KNAPP, of New York, gave a summary of the results in these cases which had been previously reported in series of 100. The results in the different series were, in percentages, given as follows:

Series.	Good.	Moderate.	Failures due to Suppuration.	Other causes.
First . .	70	22	3	5
Second . .	86	12	2	0
Third . .	86	9	3	2
Fourth and fifth	81	7½	8½	3
Sixth . .	89	1	8	2
Seventh . .	88	7	2	3
Eighth . .	90	8	1	1
Ninth and tenth	90½	5½	3	1

In the first series the section was made as far back as possible, and prolapse of the vitreous was frequent. In the third series the technique was considerably improved. In the fourth and fifth, Gräfe's section was practised and a piece of the capsule was removed; and scrupulous care was taken to remove from the pupil all lens substance that was bacteriologically bad by practising manipulation. After this the capsule was opened only at the periphery, and the section shifted into the peripheric circular section of Wecker. In the ninth and tenth series the operation was done with antiseptic precautions. In two cases the other eye had been lost by sympathy. Statistics show that the introduction of Gräfe's extraction reduced the cases of suppuration from ten or twelve to four or five per cent. Suppuration may commence at other points than in the corneal section. Purulent capsulitis frequently occurred in the earlier series. The reader was convinced that all suppuration was connected with the presence of germs, and paid tribute to the late Prof. Horner for his share in the introduction of antiseptic methods in ophthalmic surgery.

With regard to iridectomy, there were certain cases in which it was necessary, and other cases in which it was best.

DOES SUNSTROKE AFFECT THE SIGHT PERMANENTLY?

DR. J. A. SPALDING, of Portland, Maine, introduced the question of the permanent effects of insolation and sunstroke upon vision. So many pension claimants are now coming forward asserting that they suffered from sunstroke, and permanent loss of sight in the army, and finally became more or less blind, that it is quite desirable for the expert in examining such cases, to be supported by greater authority than he is likely to discover in any text-book or accessible literature. In point of fact, there has been reported in the vast extent of ophthalmic literature, but a single undeniable case in which sunstroke was followed by permanent blindness, and six others in which the eyes were ophthalmoscopically examined soon after the attack. In all others optic neuritis was distinctly marked, and in several vision was reduced to a low degree. Yet, ultimately, all six recovered perfect vision without much, if any treatment.

Two or three cases illustrative of the assertions of pension claimants were presented in the paper, and the precise reasons for granting, or not granting, a pension were reported in full. Judging from the history of these cases, insolation had nothing whatever to do with the loss of sight; whilst from historical and scientific records it appears extremely doubtful whether the disease ever has any permanent effect on the sight. The frequent allegations of patients "losing their sight during a sunstroke," or of a dimness coming over their eyes are simply descriptive of the incipient stage of unconsciousness; and are untruthful in a scientific point of view. These recollections become in later years the basis of pension claimants' assertions that their vision was seriously affected by sunstroke. Dr. Spalding expressed the opinion that these were false; and hoped that the members would support expert examiners against the insults of politicians and claimants' friends for refusing to grant pensions for asserted blindness fifteen or twenty years after a sunstroke.

DR. E. JACKSON, of Philadelphia, had found that the diagnosis, in the cases of those now claiming pensions, must be made very much as in the cases of hysterical malingerers. He had once seen permanent impairment of vision after sunstroke. But the impairment came on at once, the history clearly indicating meningitis, both disks presented the appearances of post-neuritic atrophy; and the fields of vision, particularly for colors, were irregularly contracted.

A CASE OF PROBABLE QUININE AMAUROSIS.

DR. D. B. ST. JOHN ROOSA, of New York, reported the case of a lady who had intermittent fever for some weeks during the summer. In October, when apparently well and not menstruating, she was suddenly seized with convulsions and became unconscious. Four, thirty-grain doses of quinine were given per rectum. By the third day she had recovered consciousness. Vision-counting fingers at four feet; papillæ white, retinal surface uneven. She took quinine three times a day; and strychnia was given hypodermatically daily, in increasing doses until the limit of tolerance was reached at one-twenty-fourth of a grain. After seven weeks her best vision, which had at first been eccentric, was centric; enabled her to see large objects at a distance, and small objects near, and to read No. 2 of Jäger's scale. In May, her sight had greatly improved, and later she was seen walking about the city without attendance.

DR. E. GRUENING, of New York, had seen a lady of fifty, who, after one thirty-grain dose of quinine, had remained deaf for twelve hours and blind for twenty-four hours. Five days later, in both eyes, the fundus and central vision were normal, and color perception good. But the fields of vision were greatly limited; extending not over thirty degrees in any direction. Cases of slight quinine amblyopia were rarely recorded.

DR. G. C. HARLAN, of Philadelphia, had seen cases of hysterical amblyopia that resembled the one just narrated.

DR. GRUENING said that the attending physician wrote to him that this patient was hysterical.

DR. ROOSA said that it has not been established to his satisfaction that ischæmia is the primary lesion in quinine amaurosis. Experiments upon the drum membrane of the ear indicate that the primary lesion is not ischæmia, but congestion.

CLINICAL CONTRIBUTIONS TO THE STUDY OF RING SCOTOMA.

DR. SWAN M. BURNETT, of Washington, gave the full histories of two cases of this affection which he had an opportunity of noticing through a period of two years. In only one case was there a history of syphilis, but in both there was choroiditis with vitreous opacities. The gross changes of the choroid, which were found in only one case, did not correspond in any particular with the defect in the visual field. In one case the affection was monocular, there being iritis with adhesions in the other eye. In one case the trouble began as a typical right hæmianopsia, with left semi-annular scotoma. The central clear field, which was more or less oval in form, ten degrees by twenty degrees, was never throughout all the changes essentially diminished in size.

All writers on the subject (a full bibliography was appended to the paper) have placed the pathological process inside of the eye, though in no case were the choroidal changes, manifest under the ophthalmoscope, of a character to justify such a conclusion; and in none have the changes in the visual fields been followed so closely or for so long a time as in these cases; eighteen diagrams of the fields, taken at various times, being exhibited, the course of the nerve fibres in the tract, chiasma, and nerve, as demonstrated by Burrge, Bossius, Samelsohn, Leber, and others, particularly in the somewhat analogous condition of central scotoma; which, in nearly every instance, coincided with the central clear space in these cases, seems to justify the assumption that the fibres supplying the intermediate parts of the retina were hindered in their function, either by a localized neuritis or pressure from adjoining parts.

DR. H. D. NOYES, of New York, had habitually searched for this defect in cases of retinitis pigmentosa. He remembered finding it in one such case, which long remained stationary. Another was a case of a girl of seventeen, previously treated for refractive trouble, who came for pain and dimness of sight in one eye. There were no ophthalmoscopic changes, no local lesion, no brain trouble, or hysteria. Pressing the globe into the orbit caused pain. This was taken as evidence of an orbital neuritis. Complete recovery occurred in two weeks. If systematically looked for, this condition would probably be found to be more frequent than is now supposed.

DR. C. S. BULL reported the case of a man, aged thirty-six, who had fallen when two years old, injuring the right orbit; and again, seventeen years ago, injuring the left parietal region. The second injury had been followed by epileptic seizures which were becoming less frequent. Vision, R. E. counting fingers at two feet, L. E. $= \frac{20}{xx}$ — at the centre of the field. Within two years his condition remained the same.

DR. H. KNAPP had seen one case with neuro-retinitis and ring scotoma. The eye afterward became blind with glaucoma. There were no ophthalmoscopic appearances corresponding to the scotoma. In the other eye there was no change in the retinal pigment, no excavation of the disk, and no scotoma.

DR. W. F. MITTENDORF, of New York, had seen a case in an elderly gentleman with partial atrophy of the nerve. It extended from about five to fifteen degrees. There was no corresponding lesion of the fundus. The scotomata mentioned have been near the centre of the visual field. Recently attention has been called to the existence of ring scotoma near the periphery of the field in glaucoma; on searching for it he had found it once among five or six cases. There was no change in the ophthalmoscopic appearances of that part of the retina.

DR. O. F. WADSWORTH, of Boston, had reported a case affecting one eye, in a man aged twenty five, who had been run over by a wagon. At first there was hemorrhage into the right eye and central scotoma. In a short time the hemorrhage cleared up, and the central became a ring scotoma, with central vision $= \frac{14}{x}$. The zone of blindness was about one and a half feet across at a distance of fourteen feet. This condition remained unchanged for at least two years.

THE SO-CALLED ORTHOPEDIC TREATMENT OF PARALYSIS OF THE OCULAR MUSCLES.

DR. C. S. BULL, of New York, in view of the unsatisfactory results obtained by the use of drugs, and of electricity, had made trial of the method proposed by Prof. Michel; which consists in seizing the insertion of the muscle into the sclera, with a pair of forceps, and dragging the globe alternately in the direction in which the muscle should draw it and in the opposite direction. This was kept up for two minutes at a time, and the sittings repeated daily. Brief abstracts of twenty-one cases were presented with the results obtained. Most of these were palsies of the external rectus of syphilitic or rheumatic origin. The duration of the paralysis varied from a few days to years, some gave histories of previous attacks followed by complete recovery. This plan of treatment seemed to effect a complete cure in eight cases, notable improvement stopping short of complete recovery in six cases, while in seven it proved valueless. Most of the recoveries occurred in recent cases, although in some a cure was effected after the complete failure of drugs and electricity. Without the use of cocaine the pain caused by the operation was quite severe, and even with cocaine it was always entirely painless. Marked conjunctival irritation was caused by the pinching, but this was local and transient.

CASE OF RECURRENT PARALYSIS OF THE MOTOR OCULI.

DR. O. F. WADSWORTH, of Boston, reported the case of one of a pair of twins, sisters, born of healthy parents who had in all seven healthy children. In 1874 when three years old, both had scarlet fever and subsequently discharges from their ears. In 1877 the other twin had headaches and convulsions, and well-marked optic neuritis which passed into atrophy; later the headaches ceased and she continued well. The patient had in 1878 severe headache several hours every week. In 1879 she came for headache which had lasted two weeks of an intermittent character. It began about noon and continued until 3 P.M., then it would intermit until 5 P.M., when it would return and continue four or five hours. R.E. normal and emmetropic, L.E. highly myopic and amblyopic. In March, 1880, there were headache and vomiting and an attack of ptosis with divergence of the right eye. There was now acute inflammation of the left ear. The pain was always in the

right supraorbital region. In February, 1887, she was well, except attacks of headache with ptosis and dilated pupil, which occurred three or four times a year. She was now recovering from one of these, there being oculomotor paresis still present. The interval between the last attacks had been seven or eight months. Each attack was accompanied with a discharge of offensive fluid from the right ear which lasted some days.

March 4th there was much improvement. April 24th there remained slight ptosis, and impairment of upward and downward motion, pupil slightly dilated, and accommodation weak. A large polypus was found in the right ear, which would account for temporary retention of pus. Fifteen cases of this affection had been recorded, but often very imperfectly. The statement was often made, as by this patient, that during the intervals recovery was complete, but in none was it noted that the observer himself had seen such complete recovery. There was no instance of permanent relief; but three deaths. It was difficult to admit that this disease was purely functional or nuclear in its origin. Its origin from disease about the base of the brain was more probable, and this view was supported by autopsies.

LOCALIZED HYPERÆMIA IN MUSCULAR INSUFFICIENCY.

Dr. J. A. Lippincott, of Pittsburg, had seen three cases in which the main complaint was of a congestion of the nasal side of the eyeball. Two of these he narrated. One in a colored barber, aged twenty-four. The congested area was sharply limited, had the form of a pterygium, extended nearly to the edge of the cornea, and involved both deep and superficial vessels, but principally the former. There was frontal headache, and fatigue on working or reading. This had lasted six weeks; and astringents had been used without benefit. The Gräfe test showed decided insufficiency of the internal recti muscles. Strychnia was ordered and in eight days the congestion had greatly diminished and the insufficiency was reduced to one-fourth its former amount. In four days more the equilibrium of the muscles was restored and the congestion and other symptoms had disappeared. The second case, a salesman, aged twenty-nine, came with similar congestion of the nasal side of the globe, of three weeks' standing. He had been reading a good deal at night. Here also there was insufficiency of the internal recti. He was directed to avoid unnecessary use of the eyes, get plenty of sleep, take strychnia, and douche the eyes with hot water twice daily. Following this line of treatment recovery was complete within a month.

Dr. E. Jackson had recently heard a paper read on base-ball pitcher's arm (see The Medical News 'of July 16, 1887), in which it was urged that the disability of base-ball pitchers was caused by exaggeration of the hypernutrition which follows normal fatigue; and that the congestion involves not only the muscles, but their tendons and points of insertion as well. Might not the condition just described be exactly similar, an extension of congestion from the rectus involving the tendon and its insertion in the sclera, essentially a part of the lesion affecting the muscle, and not merely symptomatic?

CASES OF SPECIAL FORMS OF GLAUCOMA, WITH PHOTOMICROGRAPHS.

Dr. William F. Norris, of Philadelphia, reported three cases, and exhibited photomicrographs of the excised globes. The first was an acute inflammatory glaucoma, which yielded to a narrow iridectomy, which was afterward found not to involve the periphery of the iris, the eye remaining quiet for eight years. Then a second attack occurred. Iridectomy could not be performed for many days after the commencement of the attack, when a broad peripheral one was made. But the eye never became entirely quiet. Sclerotomy was subsequently done. Later, intraocular inflammation with hypopyon occurred, and the eye was enucleated; the other eye remaining quiet and serviceable. Section of the enucleated globe showed, in a cystoid cicatrix, the stump of the iris left at the original iridectomy. The scars left by the second iridectomy and the sclerotomy were firmly united. The microscopical examination showed a degeneration of the head of the optic nerve, probably a step toward excavation. There was also a marked proliferation of the neuroglia in the ciliary nerves where they passed through the sclera.

The second case occurred in a lady of seventy, under observation for hemorrhagic retinitis. There were some needles of opacity in each lens. V. = R. $\frac{10}{C}$, L. $\frac{20}{CXX}$. New hemorrhages occurred in the right eye; vision still further obscured, and the globe hard. An iridectomy was done, the anterior chamber filling with blood during the operation. On the fourth day, and again on the ninth, there occurred renewed attacks of pain and further impairment of vision, apparently due to intraocular hemorrhage; by the twenty-fourth day light-perception was lost. Three days later, an attempt was made to do a neurectomy on the eye; but there occurred such profuse hemorrhage into the capsule of Tenon that it became impossible to replace the globe, and it had to be enucleated. The left eye, which had regained V. = $\frac{20}{LXXX}$, slowly grew worse until the patient died, two years later, of apoplexy. The microphotograph showed hemorrhages into the retina, and also into the sclerotic near the canal of Schlemm. It was notable in this case that retinal hemorrhage was the immediate cause of the attack of glaucoma, and that hemorrhage into the capsule of Tenon prevented the completion of the neurectomy.

In the third case, a successful cataract extraction had been done ten years before; the patient being afterward able, with glasses, to do laboring work. After eighteen months, a needle operation was done on that eye, and from that time it refused to become quiet. Subsequently it became hard, and was enucleated for sympathetic irritation of its fellow. Each end of the scar of the periphero-linear incision presented a cystoid cicatrix.

The photomicrographs of these cases all showed the imperfect approximation of the lips of the wound from the overriding of the corneal flap, An examination of Becker's plates showed the same overriding in the majority of cases; in but two was the approximation nearly accurate, and in two the overlapping was the other way. This seemed to show the need for quiet of the eye and quiet of the patient until the corneal union was firm, after iridectomy or cataract extraction.

Dr. H. D. Noyes said that in a case reported last year, dying on the fifth day, perfect approximation was prevented at one end of the incision by swelling of the scleral lip of the wound, which was double the thickness

of the cornea [illegible]. Into the space so left the iris had been forced, thus illustrating the beginning of a cystoid cicatrix.

DR. H. KNAPP asked whether the swelling of the scleral lip might not be due to the previous incarceration of the iris in the wound.

DR. NOYES believed that the use of the spatula in dressing the wound had left it free from iris.

DR. B. A. RANDALL said that in Dr. Noyes's case the anterior chamber must have been obliterated and the posterior capsule pushed forward, for the sections showed pigment attached to the posterior capsule.

SARCOMA OF THE EYELID, SIMULATING MEIBOMIAN CYST.

DR. B. A. RANDALL, of Philadelphia, presented the notes of such a case occurring in a man of forty-one, who came under his care in 1885, with the history of two operations, in the three previous years, for the removal of a cyst. The tumor had the position, size, color, and apparent fluctuation of a chalazion; but a vague grayness suggested pigmentation, and led to its removal by a V-shaped incision through all the tissues of the lid. Section proved the tumor to be a solid encapsuled sarcoma of large spindle-cells. The patient passed out of sight for two years, and then returned with a recurrence very like the original, which had also been treated in the interim as a chalazion. The outer half of the lid had now to be removed, and the tumor was found to be of the same nature as before, and again encapsuled. The Meibomian glands each time seemed normal, and the tarsus was entirely uninvolved.

SOME CASES OF CILIO-RETINAL VESSELS.

DR. B. A. RANDALL also presented sketches of the ophthalmoscopic appearances in some cases of this anomaly, and showed a photomicrograph of such a case from the collection of Prof. Norris. He remarked that such cases are far from rare, and that the occurrence of such an origin of even a principal artery or vein, supplying sometimes two different quadrants of the retina, had come to notice. As to the origin of these vessels, in two cases they could be distinctly seen to join the network of the choroid. The reported cases, anatomically examined, had been seen to arise directly from the short ciliary arteries, as in the photomicrograph shown.

THE HOHLSCHNITT OF V. JÄGER IN THE EXTRACTION OF CATARACT.

DR. RANDALL called attention to this operation as differing from the modified linear extraction only in the knife with which it is executed. To this knife he asked attention, with the claim that with it almost all of the usual modifications of the linear extraction can be made; but that no aqueous need be lost until the completion of the incision, and that consequently the cut can be made more safely and smoothly than is possible with the Gräfe knife. As illustrative of the perfection of the healing, he demonstrated a photomicrograph of a *hohlschnitt* executed by v. Jäger himself, which he had cut in Prof. Arlt's laboratory, about a year after the operation.

DR. KNAPP had used Jäger's knife, but thought it harder to manage because of its greater size. With the Gräfe knife one can withdraw slightly and rectify any mistake in the position of the counter-puncture.

DR. H. D. NOYES agreed with the last speaker as to the superiority of the Gräfe knife. He had long practised a manœuvre, which he found Panas also employed; after making the counter-puncture, the handle is rather depressed, so as first to make the portion of the section adjacent to the counter-puncture. This quickly carries the cutting edge of the knife to the border of the anterior chamber, where the iris can no longer fall before it. Then the handle of the knife is raised as the section is completed.

DR. S. THEOBALD, of Baltimore, thought the greater convenience of the narrow knife due to the fact that with it we can first make the counter-puncture, and afterward complete the section; with the broad knife both must be done at once.

DR. RANDALL said that if the puncture is made right, with the knife in the proper position, the counter-puncture must of necessity be right also; and the incision made is perfectly smooth.

DR. KNAPP thought that a broad knife acts more as a chisel, tending to push the cornea before it.

DR. E. GRUENING was of the opinion that the difficulty about making a counter-puncture is that its location is not seen; and when an attempt is made to correct its position, aqueous escapes and the iris is apt to fall before the knife.

(To be concluded.)

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, held at Long Branch, N. J, July 21, 22, and 23, 1887.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, JULY 20TH.—MORNING SESSION.

DR. CHARLES K. MILLS, of Philadelphia, the retiring President, in a few remarks presented DR. LANDON CARTER GRAY, of Brooklyn, the President-elect.

DR. E. C. SPITZKA, of New York, read a paper on

SOME POINTS REGARDING THERAPEUTICAL AND OTHER INJURIES OF THE BRAIN.

In the course of certain experimental injuries undertaken between eighteen and three months ago, he made some observations which appeared to be novel. The experiments varied from the excision of an entire hemisphere, simple trephining and the introduction of foreign substances into the arachnoid cavity, to the injection of substances into the brain tissue directly, into the ventricular cavities, and into the arachnoid sacs at the base of the brain. Trephining necessarily preceded the introduction of the hypodermatic needles in the latter instances. He witnessed in one instance an extensive operative exposure of the human brain, and made the post-mortem analysis in two cases where operations had been attempted or made in accordance with the modern teaching of cerebral surgery. The results to which he especially directed attention, are those relating to the healing of wounds made by hypodermatic needles and trocars.

He held that in young persons, even under discouraging circumstances, as wounding of the dura by the saw, the dura makes successful efforts to agglutinate the removed button and restore the integrity of the calva-

rium. In connection with a number of cases where trephining was practised, he had found that the larger the opening the less is the probability of protrusion of the brain.

The observations made with hypodermatic and other needles on the brains of dogs, relate to these points.

First to the formation of cerebral abscesses at points remote from the point of injection of septic material. His experience with animals would seem to indicate an enormous individual difference. On the one hand, coarse needles have been inserted, coarse substances injected, the animal killed after a month, and not the slightest trace of the channel or the point of penetration found. On the other hand, comparatively innocuous substances have been injected with fine needles, and, the animal being killed after a year, the tract of the needle found as fresh as if it had been made a few hours before.

From his limited experience with the human subject and observations in experimental pathology, he drew the following conclusions:

1st. That exploratory needles should never be introduced into the internal capsule, the contiguous ganglia or lateral ventricles, merely for exploratory purposes unaided by positive clinical indications of the location of disease.

2d. That exposures of large surfaces of the brain are not feasible in persons with feeble vascular walls, owing to the dangers of intracranial hemorrhage.

3d. That buttons which have been reinserted under aseptic precautions are, even in the event of non-union, entirely harmless.

4th. That in young persons buttons of bone may become reunited to the calvarium even though perfect coaptation be not assured.

He added that he has very recently experienced how desirable it is that in the event of trephining for the relief of cortical irritation, that on removal of the latter the button of bone be replaced.

DR. G. HAMMOND thought that in all cases of trephining the button of bone should be reinserted; and he quoted a successful case of Dr. Weir, in which a large piece of bone had been removed, and afterward reinserted with the most desirable results; the portion replaced having united firmly to the calvarium.

DR. LLOYD asked if Dr. Spitzka had ever punctured the brain of a child for hydrocephalus; as some time ago he had a patient brought to him for this purpose.

DR. MILLS thought it perfectly right in some cases to reinsert the button of bone, but, at the same time, the condition of the dura must guide us in the matter, as to the extent of inflammation exhibited; he quoted one case in which the piece of bone removed was three by four inches, but there was a central depression in the bone removed, and it was deemed necessary, in order to insert the bone, that this depressed portion be removed; the bone, however, was not replaced. In regard to the remark made by Dr. Spitzka, as to the animal brain being more resistant after surviving the first operation, that had been corroborated by his own experience. He mentioned a case in which the portion of bone removed was the largest he had ever seen, accompanied also with considerable loss of blood; the patient made a good recovery after the operation, but afterward died from pneumonia.

DR. SPITZKA said that in those cases in which it was not deemed advisable to reinsert the bone, he believed that the method of sprinkling the exposed surface of the dura with bone grafts was advisable, and he thought that even should a bone graft drop into the brain substance, it would do no harm, as the bone dust in trephining in some cases has caused no disturbance. As to the question asked by Dr. Lloyd as to puncture of the brain for hydrocephalus, he would not hesitate to insert a large trocar into the brain substance, although he had not performed the operation, he had seen Dr. Detmold do it, and he had himself tapped large tumors of the brain with the most satisfactory results.

DR. JAMES J. PUTNAM, of Boston, presented the

NOTES OF A RARE CASE OF DYSTROPHY OF THE FACE AND HEAD.

The case was one probably of hyperostosis of the cranium, occurring in a young woman twenty-one years of age. Her health was apparently good, and there was no history of syphilis; her mother, however, suffered with her head. The first symptoms were severe, and intense pains in her head, enlargement and protrusion of the eye were first noticed about two years after the beginning of the headache. Three years ago her teeth began to fall out, and at the time he saw her she had but one remaining tooth. Two years since, a purulent discharge from the ears appeared, and she could not distinguish the sound of a tuning-fork. Two years after the onset of the symptoms she had a miscarriage, and one year later menstruation ceased. There was œdema of the left eyelid, the eyes were extremely protruded, so that more than half the globe projected; there was no evidence of any paralysis of the nerves, except that the tongue moved slightly to one side. There was a well defined opacity in the upper cortical lens of the left eye, which may be of importance.

DR. PUTNAM then made a few remarks upon a case of

SARCOMATOUS TUMOR OF THE BRAIN

attached to the sphenoid bone. The patient had had attacks of periodical headache eighteen months previously, which he thought might be ascribed to this cause. During the time he had seen her she suffered from intense headache and neuritis, and then eventually a slight degree of facial paralysis on the opposite side; in the last two months she had complained of the two middle fingers of the left hand on the side of the tumor. At the autopsy the brain exhibited a shining black mass, representing a flattened tumor. This contained blood with a small number of cysts, and in spite of the remarkable pressure they produced, no distinctive symptoms presented themselves until within the last two months. It is an interesting surgical question as to whether in this case an exploratory operation would not have been justifiable.

DR. SPITZKA remarked that in one case where the numbness occurred in the fingers as mentioned by Dr. Putnam, a tumor had been discovered in the brachial region.

DR. PUTNAM said the autopsy was confined to the head alone. He thought Dr. Spitzka's remark just; as he could call to mind a case in which a tumor of the brain was pressing on both hemispheres and which presented no symptoms but pain and numbness in one

wrist; but in the case first mentioned the pain was not in the ulnar nerve, it was only in the two middle fingers. He said that Charcot had noted the same thing many years ago.

AFTERNOON SESSION.

DR. C. L. DANA, of New York, read a paper on

HEREDITARY TREMOR.

DRS. PUTNAM and DERCUM mentioned cases coming under their notice with the same symptoms described.

DR. HAMMOND asked Dr. Dana if he considered this the only form of hereditary tremor, he remembered a case in which the patient could not sit in a chair; his affection was similar to chorea in its manifestations. He could only trace it back to the mother in this instance, his brother and sister had it, and also a niece, it did not appear in this man until he was thirty-five years old, and toward the end of his days mental failure, delusions, hallucinations, etc., set in.

DR. DANA replied that the tremor he had described in his paper was by no means rare and he was surprised that it was not mentioned in our literature.

DR. GEORGE W. JACOBY, of New York, read a paper on

MICROSCOPICAL STUDIES IN A CASE OF PSEUDO-HYPERTROPHIC PARALYSIS.

From his investigations, if he might draw conclusions without at the same time generalizing, he should in a measure differ from some observers, being convinced that in many patients the disease is essentially a chronic inflammation invading both the perineurium and the muscle tissue. He considered it impossible to say what the cause of this process might be unless sought for in a congenital malformation of the muscle tissue itself, such malformation being indicated by the small size of the sarcous elements, as we are accustomed to see them in the earliest stage of embryonal development.

But, however this might be, the pathological process consists of a gradual reduction of the muscle fibres into medullary or inflammatory corpuscles, which, in turn, go to build, partly fibrous, partly cartilaginous, and partly fat connective tissue. The process, which is extremely slow, gradually leads to an augmentation of myxomatous or other varieties of connective tissue at the expense of the muscle tissue. He placed the whole process, as seen in his specimens, in the same category with the process termed myositis ossificans progressiva; had he to describe it in a few words he would call it a *myositis progressiva hyperplastica*.

DR. DERCUM stated that he had examined some typical cases last fall occurring in the adult. Also a case in which there were some signs of inflammatory changes in the corpuscles and connective tissue element, in these cases there was a myositis, interstitial myositis, but whether it was secondary to the myositis proper it was difficult to say.

DR. SACHS, of New York, presented a paper on

ARRESTED CEREBRAL DEVELOPMENT WITH SPECIAL REFERENCE TO ITS PATHOLOGY.

He reported a case of a child which was perfectly formed in its limbs; before birth, however, the mother was thrown from a carriage. There were symptoms also of mental weakness on the side of the parents. The child would lie on its back and never attempt voluntary movement; objects placed in its hands would fall out; as it grew mental vigor did not increase, and finally total blindness set in. The child never uttered a sound except a low gurgling noise if left alone. There was no rachitis, no history of syphilis, and the child finally died from pneumonia. At the post-mortem the skull was found to be thickened and a large clot in the longitudinal sinus, the brain weighed two pounds, and the bloodvessels appeared to be normal.

DR. AMIDON had seen two cases very much like this in which there was no lesion apparent, but there were signs that hemorrhage had occurred some time before. He thought hemorrhage might occur without leaving any trace at the autopsy, and he asked Dr. Sachs whether it occurred to him that it might have been the same in his case.

DR. SACHS thought that if hemorrhage had occurred there would be thickening of the cortex. The child at birth was brighter than later on in life. He did not think the condition was owing to traumatism, but rather that the general circulation and nutrition had been disturbed.

(To be continued.)

CORRESPONDENCE.

THE NEW YORK STATE BOARD OF MEDICAL EXAMINERS.

To the Editor of THE MEDICAL NEWS.

SIR: A law of 1874 established for the State of New York a State Board of Medical Examiners. Frequent deaths and occasional resignations changed its original membership several times, until, upon the recommendation of the undersigned (who therefore objected repeatedly to his own appointment) and for reasons easily understood, all the members of the present Board, with one exception, were selected by the Honorable the Board of Regents of the University of the State of New York, from amongst the medical men of Albany, the seat of the government and the Board of Regents.

The profession never expected the law as it was passed in 1874 to be efficient. It was believed by many that some of the medical colleges objected to the establishment of a State Board altogether, though others were known to favor it. It was certain that sectarian influences succeeded in undermining the passage of the original bill and emasculating it. *It is certain* that no State Board of Examiners will ever benefit either the profession or the public, both of which stand in equal need of it, before the license to practise medicine will depend on the *compulsory* passing of a successful examination before the State Board. As the law stood, nobody ever applied for examination and the degree of M.D. of the University of the State of New York, who was in the possession of a diploma from a college in good standing. Such few as volunteered to come forward, were men who had previously failed in their college examination, or "practised medicine" without study, knowledge, or any title whatsoever. There being no rules and regulations referring to a minimum of accomplishments or requirements, a few of these were let loose upon the unsuspecting public with a diploma; the majority, however, failed.

When the new Board was appointed in the beginning

of this year, its members accepted their positions upon the condition that the Board of Regents would authorize a number of rules and principles which were to regulate the examinations, and the granting of degrees. As they have been approved by the Regents, I am directed by the Board of Examiners to present them to you for your information, and, if you deem proper, for publication and comment. We know quite well that, as long as the examination by the State Board is not made *compulsory*, any number of rules and principles will prove their inadequacy and inefficacy again and again. But the present Board hopes that its earnest recognition of the rights and dignity of medical science, art, and practice will be admitted by, and found acceptable to the profession, and that the latter, after a minimum of requirements for the admission into the ranks of the profession has been officially accepted by the Regents, will feel encouraged to continue its exertions in behalf of both the elevation of the standard of medical education and the protection of the public.

Not one of the recent applicants for a degree has proved successful. One of them had failed in his college examination a few weeks previously, and now threatens to swell the number of graduates of the "University" of a neighboring State.

Very respectfully,

A. Jacobi, M.D.

110 West 34th St., New York,
July 25, 1887.

Rules for Examination.

The members of the State Board of Medical Examiners accept their positions with this understanding:

A candidate for the degree of Doctor of Medicine to be given by the Board of Regents, either desires an additional degree after he has received his diploma from a chartered medical college, or he has no diploma from any chartered medical college, and desires or prefers one from the Board of Regents. The degree given by the Board of Regents is to be, or become, an honorable distinction. It must be the object of the law to protect the people and to ennoble the medical profession, and not to facilitate the entrance into it of persons unfit or unqualified. The profession does not require larger numbers, but does insist upon an elevated standard. Therefore the examination must be strict, and must be conducted according to the following rules:

1st. The examinations before this Board shall be conducted in the English language exclusively.

2d. The candidate shall be allowed two and a half hours for each examination. The examination shall be in writing. The candidate must not consult books, extracts, notes, or persons, and must not communicate with any one during the two and a half hours allotted to him. To do so is to be considered a failure to pass.

3d. The examination in clinical medicine and in clinical surgery shall consist in the actual examination of patients by the candidate, and a discussion in regard to the diagnosis, prognosis, and treatment of the cases.

4th. The examination in chemistry shall include the actual testing of a specimen of urine, in regard to its reaction, specific gravity, and the presence or absence of albumen and sugar.

5th. Each Examiner shall have the privilege, if he so desire, of supplementing his written examination by an oral one, in the presence of two other members of the Examining Board.

6th. The scale of marks shall be from zero to ten; ten being perfection, and anything below six being a failure to pass the examination.

7th. The questions and answers with their marks shall remain in the possession of the Board of Regents, and shall be open to inspection.

8th. When the candidate shall have completed all his examinations, the Board of Examiners shall meet and hear the result of the examination in each branch. And within ten days thereafter, each member of the Board shall make a written report as to the merits and acquirements of the candidate; being guided in this report, not alone by the result of the examination in his particular branch, but also by the result of the examinations in the other branches. And each member of the Board shall send his report, together with the questions and their answers and their marks in his branch, to the Secretary of the Board of Examiners; to be by him transmitted to the Secretary of the Board of Regents.

And furthermore it is the opinion of the Board of Examiners: that in order to receive the degree of Doctor of Medicine, the candidate should successfully pass in every branch; or at least in every branch but one.

State Board of Medical Examiners.

President, Abraham Jacobi, M.D., Examiner in Pathology.

Vice-President, Albert Vanderveer, M.D., Examiner in Surgery, and Clinical Surgery.

Secretary.—Henry Hun, M.D., Examiner in Clinical Medicine, and in Materia Medica and Therapeutics.

James P. Boyd, M.D., Examiner in Obstetrics.

Franklin Townsend, M.D., Examiner in Physiology.

Samuel R. Morrow, M.D., Examiner in Anatomy.

William Hailes, Jr., M.D., Examiner in Histology.

Willis G. Tucker, M.D., Examiner in Chemistry.

NEWS ITEMS.

Nova Scotia Medical Association.—The nineteenth annual meeting of this Association was held at Truro, N. S., beginning July 6, 1887.

The following officers were elected for the ensuing year:

President.—Dr. William McKay, M.P.P., of Reserve Mines.

Vice-Presidents.—Drs. D. A. Campbell, of Halifax, and W. B. Moore, of Kentville.

Secretary and Treasurer.—Dr. W. S. Muir, of Truro. Digby was chosen as the place of meeting next year.

Gaseous Enemata in Bellevue Hospital.—The use of these enemata has been entirely abandoned in the fourth division, Bellevue Hospital, where they have been earliest and longest tried.

A Sanitary Congress in South America.—The Peruvian government has invited the republics of Central and South America to coöperate in the formation of a sanitary congress to be held at Lima, November 1st.

It is a significant sign that these governments, so sorely tried by the hardships accompanying contagious diseases, are at last awakening to the importance of undertaking preventive measures.

FREE COMPETITION FOR POSITIONS IN THE HOSPITALS OF NEW ORLEANS.—Dr. Joseph Jones, of New Orleans, introduced at the recent meeting of the Louisiana State Medical Society, a resolution calling upon the Legislature to repeal the law of 1885 excluding all medical students from competition for the position of resident students of the Charity Hospital, except native and residents of Louisiana.

AN HONOR DECLINED.—PROFESSOR GAIRDNER, of Glasgow, has declined the honor of knighthood offered him on the occasion of the recent jubilee of the Queen.

BROMIDIA.—The United States Circuit Court has granted a perpetual injunction restraining the publication of a formula for a liquid medical preparation under the name "bromidia," unless there is also published, in connection with the said words "bromidia," or "bromidio," a statement that the preparation covered by the said receipt is put up and sold by Battle & Co., of St. Louis, under the trade-mark "Bromidia."

LEAD POISONING FROM HATBANDS.—Dr. Joseph F. Gerster, in the *American Grocer*, describes a case of poisoning from wearing a hat with sweat-bands colored with lead. The chief symptom was headache. It is not uncommon to use lead in preparing the leather for sweat-bands, but there is rarely any dangerous amount.

ANALYSES OF MILK SOLD IN NEW YORK.—The *World's* analyses of milk sold in New York City and consumed by the defenceless babies of the metropolis, shows over one-quarter of the samples examined to have been skimmed or watered. The advisability of permitting skimmed milk to be sold if the receptacles from which it is sold are marked to that effect, has been discussed freely, but the board of health is of the opinion that its sale should be entirely prohibited. The sale of milk is one of the most perplexing things to control which a board of health is compelled to meet. Its sale is carried on by such a multitude of people for a short portion of the day only, and it is delivered in such small lots that interference with it can be but infinitesimal at best. Dealers should be taught to look for inspection any time, and caused to fear the subsequent publicity which should follow detection. In that way the fraudulent substitution of skimmed milk for milk of legal standard may be lessened. Another good plan would be for every purchaser to inform his milkman that it is proposed to have a sample of the milk submitted to the health authorities for examination. This would put the dealer in the way of delivering a better article.—*Sanitary News*, July 9, 1887.

IN MEMORY OF DR. J. C. HUTCHISON.—At a special meeting of the Board of Managers of the Alumni Association of the Long Island College Hospital, held July 20, 1887, convened to take action in the matter of the death of Joseph C. Hutchison, M.D., LL.D., late president of the Collegiate Department, the following preamble and resolutions were adopted.

Whereas, In the death of Joseph C. Hutchison the College has lost an able worker, in his recent official capacity, and one to whom it was indebted for a more active part in the past as professor of surgery, and believing the reputation and honor of the institution rest in the hands of its teachers, it is

Resolved, That one who showed such boldness and fidelity in defending its best interests, is worthy the highest praise and respect of this Association.

Resolved, That the Association extends its heartfelt sympathy to the family of the late Dr. Hutchison, and its condolence to the Board of Regents of the Long Island College in this our common affliction.

Resolved, That a copy of these resolutions be sent to the family of Dr. Hutchison, the Board of Regents, and the press.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JULY 19 TO JULY 25, 1887.

HEGER, A., *Lieutenant-Colonel and Surgeon.*—Assigned to duty as member of the Army Retiring Board, convened at Governor's Island, New York Harbor, N. Y., vice Colonel Charles Sutherland, Surgeon, hereby relieved.—*S. O. 167*, par. 13, *A. G. O.*, July 21, 1887.

By *S. O. 102*, par. 13, *A. G. O.*, July 15, 1887, so much of par. 1, *S. O. 150, c. s., A. G. O.*, as directs *Captain and Assistant Surgeon* JOHN DE B. W. GARDINER, U. S. Army, to report for duty at Fort Washakie, Wyoming, is revoked.

COWDREY, S. G., *Captain and Assistant Surgeon.*—Granted one month's leave, to take effect on or about July 24th.—*S. O. 79, Department of Texas*, July 13, 1887.

BARNETT, R., *Captain and Assistant Surgeon.*—Sick leave still further extended six months, on account of sickness.—*S. O. 162, A. G. O.*, July 15, 1887.

By *S. O. 162*, par. 43, *A. G. O.*, July 15, 1887, so much of *S. O. 150, c. s.*, par. 1, *A. G. O.*, as relieves *Captain and Assistant Surgeon* GEORGE H. TOMEY U. S. Army, from duty at Fort Monroe, Virginia, is revoked.

TAYLOR, A. W., *Captain and Assistant Surgeon.*—Now at Fort Laramie, Wyoming, is ordered for temporary duty at Fort Robinson, Nebraska.—*S. O 162, A. G. O.*, July 15, 1887.

BLACK, C. S., *First Lieutenant and Assistant Surgeon.*—Ordered for duty as Post Surgeon, Fort Bliss, Texas, during the absence on leave of Captain S. G. Cowdrey, Assistant Surgeon.—*S. O. 79, Department of Texas*, July 13, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING JULY 23, 1887.

FESSENDEN, C. S. D., *Surgeon.*—Granted leave of absence for thirty days, on account of sickness, July 18, 1887.

MEAD, F. W., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, July 19, 1887.

YEMANS, H. W., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, July 23, 1887.

BROOKS, S. D., *Passed Assistant Surgeon.*—Promoted and appointed Passed Assistant Surgeon from July 1, 1887. July 21, 1887.

WHITE, J. H., *Assistant Surgeon.*—To proceed to Washington, D. C., as escort to an insane seaman, July 18, 1887. Ordered to examination for promotion, July 23, 1887.

WATKINS, R. B., *Assistant Surgeon.*—Leave extended fourteen days, on account of sickness, July 20, 1887.

MAGRUDER, G. M., *Assistant Surgeon.*—To proceed to Galveston, Texas, for temporary duty, July 21, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LI. SATURDAY, AUGUST 6, 1887. No. 6.

ORIGINAL ARTICLES.

ON HORNY GROWTH OF THE PENIS.[1]

BY JOHN H. BRINTON, M.D.,

PROFESSOR OF PRACTICE OF SURGERY AND CLINICAL SURGERY IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

JOHN B., aged sixty-two, a farmer, presented himself at the clinic of the Jefferson Medical College, on the 8th of October, 1886. He stated that he had upon his penis a horn, which had existed for more than four years, and which had originally grown from a wart. The wart was of some size, and at times itched greatly, and he was in the habit of rubbing it to relieve this disagreeable sensation. All that he could say of the growth was that the wart gradually turned into horn which slowly increased in size. It was, however, painless, and caused him no trouble, except that it mechanically interfered with coition.

On examination, a large, horny growth was found springing from the base of the glans, at the coronal border, and firmly attached both to the gland and to the prepuce. The horn was one and seven-eighths inches long, one and three eighths in circumference at its base, and curved forward, tapering slightly, beyond the extremity of the glans. On the dorsum (Fig. 1), half an inch in front of the corona, a

FIG. 1.

plate of horny tissue, varying in width from three-quarters of an inch to an inch, encircled the end of the glans, covering and destroying the frenum and its attachment, surrounding the meatus, and narrowing it to a pin's point; through this narrowed opening, impervious to any instrument, the urine escaped slowly, drop by drop. This plate of horn presented a longitudinally striated surface, somewhat like that of an uneven or exaggerated thumb-nail, and having, when dry, a smooth and polished appearance.

FIG. 2.

The under surface (Fig. 2) of the horn and of the horny plate, seen when the penis was laid against the belly, was uneven and jagged, seemingly composed of bundles or spiculæ of horny tissue, separated, and somewhat resembling short bristles. After amputation of the glans behind the corona, a No. 1 catheter could easily be passed along the urethra from behind, until abruptly stopped by the plate of horn above referred to. The corpora cavernosa were found to be normal.

The extent of the disease was so great, and the involvement of the urethra so complete, that amputation was considered to be indicated. The glans was therefore removed by an incision just behind the corona. The patient recovered rapidly, and was discharged from the hospital on November 2, 1886.

The microscopical examination of this growth was kindly furnished to me by Dr. Morris Longstreth. The first part examined, taken from the middle portion of the horn, appeared, when disintegrated with caustic potash and mounted in glycerine, to be composed of epithelial cells of the usual squamous variety. These cells were dry, shrivelled, closely packed, and difficult of separation, even more tightly united than in the structure of living nail. This general condition was more marked in the outer or external portions of the horn. In the flat or nail-like portion covering the dorsum of the glans the same cells were found, but they were more easily separated, individually less shrunken, and corneous in appearance, and many of them showed abundant granular contents. In short, no essential difference existed in the arrangement or character of the cells of the horn proper, and of the lamellar or nail-like, horny plates covering the glans. The seeming differences were of degree rather than of kind.

[1] Read before the Association of Genito-Urinary Surgeons, at the Annual Meeting at Lakewood, N. J., May 19, 1887.

The rarity of horny growths upon the penis is somewhat remarkable, and one is surprised to find only fourteen cases accurately recorded in English, German, and French reports. A few more instances are vaguely alluded to, but in such uncertain terms as to render them worthless for study. Confining ourselves, therefore, to the trustworthy descriptions of this affection which have reached us, we find, on comparison, a singular uniformity in their description.

Horns upon the penis occur in two forms. In the first, as well-marked, projecting horns; in the second, as rough, flattened, horny plates of greater or less thickness, occupying the surface of the glans penis. In several instances, as in that before us, both of these varieties are present. Where well-marked horns exist on the penis, their bases of attachment are usually the corona, the sulcus coronalis, or the mucous surface of the prepuce. These horns, at first sight apparently single, are often multiple, one horn predominating in height and size, while a range of very much smaller like growths extend laterally along the corona. The inguinal glands are frequently affected.

As to the age at which these developments take place, it would seem that they are most frequent in advanced life, from fifty to seventy years, or even later. In the case reported by Dr. Jewett, of Connecticut, in which the horn—the largest on record—was three and a half inches long, and three-quarters of an inch in diameter, the patient was twenty-two years of age. In the case reported by Pick, of Prague, in which the horn was two and a half inches long, the patient was also twenty-two years old. In one instance observed and figured by Demarquay, the age of the patient was nineteen and a half years.

These penile projecting horns are usually curved, and project over, or to the side of the glans, are truncated toward the extremities, and are striated or corrugated longitudinally, with a tendency of the fibrillæ to separate, or split lengthwise. In color, they vary from a whitish or ash-gray to a yellowish-brown, or black. They are most often painless, but by their growth, as one might naturally infer, at first mechanically interfere with, and as they increase in size later, prevent coition.

It is difficult to understand the causes, generally, of cutaneous horns; indeed, Hebra has remarked that it is scarcely necessary to study those causes which, so far, are clear to no one. Hartman characterizes their origin by the phrases "Lusus naturæ," and "nisus exrescendi." Yet so far as horny growths from the penis are concerned, it would seem that they may be caused by the irritations peculiar to their site. Thus, it will be seen by reference to the appended cases, that in many of them an actual source of local irritation existed. Thus, in six out of the fourteen, phimosis, either congenital or acquired, was present, and the horny growths usually supervened upon the operation for the relief of this condition. We have then the irritation of the deformity, the accumulating secretions and filth, and the irritation of the operation, surely enough to give rise to a papillary hypertrophy, sufficient for the development of flattened or horny growths, or protuberances. In other cases, the horny growths on the penis have followed, or been coincident with an epitheliomatous condition, and in nearly every instance have been preceded by a wart, accompanied by more or less itching. In some instances, the removal of the horns has been followed by the occurrence of epitheliomatous growths.

It will thus be noticed that in all the fully recorded cases there is a general, and, indeed, a strong family likeness as to origin and development of the growth in question. In the case I have reported, there is one peculiarity which I have not noticed in the other instances. It is this, that the anterior one-fourth of an inch of the urethra of my patient was almost entirely occluded by the horny formation, so as to a great degree to interfere with micturition. By examination of the specimen, this horny structure will be found to be abrupt, the normal calibre of the urethra being preserved until sharply arrested by the horny plate involving the meatus.

The *treatment* of these cases may be summed up in two words—thorough removal. If the horn be single, and its attachment be circumscribed, this can be done by including in the incision a sufficient amount of soft tissues. When, however, the base of the horn is broad, when it has extended widely, or is accompanied by epitheliomatous formations, or when the urethra is surrounded, and is constricted and compressed, it would seem better, particularly in old men, to remove the entire gland.

Appended will be found references to all cases of horny growths on the penis I have been able to collect

Case I.—Caldani (*Memoria della Soc. Italiana*, F. xvi. p. 125; *Meckel Archiv.*, 1851, p. 301. Lebert, Ueber Keratose, Breslau, 1864, p. 47). A man, aged seventy, previously healthy, experienced a sudden violent itching on the outside of the right varicose leg, which he scratched until it bled. Œdema and ulceration followed, here and there, which were healed at the expiration of two years. Soon after violent itching between gland and congenitally phimotic prepuce occurred, which in his efforts to assuage, he rubbed to bleeding. After some months, a soft, sensitive mass projected from the preputial orifice; the prepuce was slit up, the cancer-like mass removed, with a small portion of the glans, and then the entire prepuce was cut away, and the wound healed in a month. Three days after operation at the incised portion of the glans, a small, hard projection appeared, which was cauterized on the fourth and fifth days by the hot iron. It disappeared, and on the eighteenth day, on the same place, two other raised spots developed. These, and a third unusual growth, evident two days later, were cauterized, and the patient left the hospital fully healed. Five days afterward, in the centre of the scar, a white, hard, insensible body appeared, which in ten months developed into a large horn, bending over the end of the glans, in front of the meatus. The reporter adds that the after-march of this case, and its termination are unknown.

Case II.—A. Richond-Desbrus (*Archiv Gén. de Méd.*, 1827, t. xv. p. 218. Quoted by Lebert, p. 48). A patient, sixty years of age, in 1825 presented for treatment. His glans penis was greatly swollen, covered with enormous, irritable bleeding vegetations. His prepuce, slit by a previous operation, was also tumefied, hardened, and covered by foul growths. The glans was covered with a black crust, and beneath this the glans

had degenerated into a white velvety tissue, which bled readily. He had never had any venereal affection. The vegetations and remainder of prepuce were removed, and surfaces cauterized. Fifteen days afterward the vegetations had returned, but operation was refused. In the next year he again presented himself; an enormous horn had now developed from the glans, similar in form, consistence, and color, to the other horn. On being burned, the odor was that of ordinary horn. Its external surface was hard, but the interior layers were friable and porous. The glans was twisted to one side, and urination was difficult. The centre was filled with a hardened caseous matter. The lymphatics of the right side were enlarged. Three months later, the irritation passed to the acute stage, the prepuce became red, hard, painful, and suppuration was established. Amputation was advised; he went up to Lyons for operation, and the reporter learned nothing further of his case. Of this patient, Lebert observes that "he probably suffered from cancroidal epithelioma of the glans, with horn complication, and that already a bubo, probably also of epitheliomatous character, existed, the issue of which is fatal. Had the patient been cured, the fact probably would have been published."

Case III.—Breschet (*Dict. de Méd.*, t. ix. p. 113, quoted by Richond-Desbrus, and by Lebert) reports having seen on a very old man, one of his patients, horny layers, which sprung from the glans.

Case IV.—Otto (*Seltene Beobachtungen, etc.*, Breslau, 1816, p. 109, quoted by Lebert) says that Dr. Ebers, hospital physician, some years since saw a man with a horn firmly attached to the glans. This horn was curved, and was greater and thicker than that described by Caldani.

Case V.—Carrow (*Bulletin de la Société Anatomique*, t. xxix. p. 235. Quoted by Lebert) describes a horn growing from the prepuce of a forester, forty-five years of age. It was situated between the hinder border of the glans and the meatus, on the left side of the frenum, and occupied the top of the glans. The blunt upper surface was dry, wrinkled, and easily split. The horn, fifteen to eighteen lines in length, was irregularly prismatic and triangular; the point was directed under and backward, in relaxation of the organ. There was no pain, but coition had for some time been impossible in consequence of the resulting pain to himself and his wife. The horn had existed for two years, and was gradually increasing. The horn was thoroughly excised, and a few days thereafter the patient left the hospital. His further history is not given.

Case VI.—Middledorpf communicated to his colleague Lebert the following case. A man seventy years of age, and for his time of life strong and well nourished, suffered ten years since from a commencing phimosis, for which no cause could be assigned. This increased to such an extent as greatly to impede micturition, and a year afterward the phimosis was operated upon. The wound healed badly, suppurated, and threw off crusts. Soon a hard, horny growth developed on the site of the excised prepuce, and increased so much in the region of the frenum that the patient cut it off piecemeal with the scissors; the upper part fell off sideways, but was reproduced. Upon the dorsum a horny growth took place at the seat of the former operation. Near the frenum, or rather on the whole under surface, a horny growth developed, formed of many single horny lamellæ cylindrically aggregated. When these plates split after the use of the scissors, the patient bound them together with a thread. He refused to be operated upon.

Case VII.—Demarquay (*Maladies Chirurgicales de Penis*, 1877, p. 330), speaking of horny growths on the gland, says: "Sometimes the horny production is single, and this is the most frequent case; sometimes there exist on the gland a certain number of horny lamellæ, as in a case which presented himself, in 1869, in my service, and which is represented in Fig. 11 (figure given showing a series of small horns from one-third to one-half of an inch in length around the base of the gland). These excrescences appeared on the gland four months since, under the form of two little 'boutons,' which persisted despite the employment of powder and appropriate pommade. Soon the 'boutons' were transformed into appendages, which increased in number and volume, and assumed the appearance they offer to-day. According to the patient, a typhoid fever which he had, and which lasted two months, in no respect modified the condition of these excrescences."

Case VIII.—Hebra (*Handbuch der Pathologie und Therapie*, II. Bd. S. 27. Quoted by Pick) refers to a case occurring in the clinic of Professor Schäbus, in Klangenfurt. In this instance a horn four inches long, of the thickness of a little finger, curved and slightly bent to one side, sprang from the dorsum of the penis, probably of the glans, although this is not stated.

Case IX.—Bergh (*Archiv für Dermatologie und Syphilis*, 1873, p. 186) refers to a case of horn growing from the "collum glandis," described by C. C. Siebold, in the *Ephem. Nat. Cur.*, vi., 1778.

Cases X and XI.—Hessberg (*Inaugural Thesis*, Göttingen, 1868, quoted by Bergh (op. cit.) and Pick, *Vierteljahresschrift für Dermatologie und Syphilis*, 1875, 2, p. 320) refers to two other cases.

Case XII.—Dr. P. A. Jewett, of New Haven, Conn., (*N. Y. Medical Times*, 1853, p. 79) reports the case of O. P. H., aged twenty-two, admitted to hospital at New Haven, August 2, 1846, for congenital phimosis, for which he was operated on, and discharged cured. On November 13, 1846, he was readmitted with extensive warty excrescences growing from the cicatrix caused by the operation for phimosis. These were treated for several weeks by caustic applications and active constitutional remedies, syphilis being suspected, but without benefit. The warts were then cut off; the wound healed well in a few days, and he was discharged cured. In the summer of 1848 the warts reappeared, and were removed at one of the New York hospitals. He was discharged well, and in three months again presented himself at the New Haven Hospital, stating that a few weeks after leaving the New York hospital he noticed on the glans a small, hard tumor, unattended with pain, but subject to paroxysms of intense itching, which continued to increase. At the time of admission to hospital, December 5, 1848, this growth presented all the appearances of a horn. It was light brown, lamellated, painless, and when burnt, as he was in the habit of doing to amuse the inmates, emitted the peculiar odor of horn. It measured three and a quarter inches in length, three-quarters of an inch in diameter at base, gradually tapering to a point. The only inconvenience was from its size and situation. It was removed by a simple incision, including the base of the horn and a portion of the glans penis. Four years after the operation there had been no return, and the organ remained perfectly healthy.

Vilieneuve has reported seventy-six cases of horns, of which three were on the penis and glans.

Case XIII.—Pick, J. T., Prof. in Prague (*Vierteljahresschrift für dermatologie und Syphilis*, 2, 1875, p. 315), reports the following:

April 13, 1874, J. W., day laborer, aged twenty-two, was admitted into general hospital at Prague, for a high grade of balano-posthitis, with congenital phimosis. The preputial orifice admits only a small sound, so that on urination the prepuce is distended, and between the prepuce and glans hard lumps and firm adhesions can be felt. A whitish, purulent fluid exudes from the preputial opening. Inguinal glands swollen and tender; no pain in urethra. No coitus has been had.

Psoriasis on scalp and on extensor side of elbow, and knee-joint. Phimosis operated on, many preputial adhesions divided, and a number of condylomata removed from the corona, and sulcus coronalis. As healing took place, the swelling of the inguinal glands disappeared; the papilloma returned, and disappeared after removal and energetic cauterization. On June 26th patient was perfectly healed, and discharged.

Nine months afterward the patient returned, with horny growth (figured in two colored prints). He stated that two months after discharge from hospital, and after slight itching of that part of the gland where formerly the papillomata were, fresh warts developed, which hard at beginning, in six months increased to their present size. Had had no coitus since leaving the hospital, and no medical treatment. The horn, attached at the junction of the gland and prepuce, was embedded as a nail in its matrix; numerous other small club-like horns sprang from the base of the gland, pointing forward, and extending laterally in their continuity half way around toward the urethra. The large horn, which curved from the right side toward the left, overhung the gland, and when the latter was laid against the belly, presented an appearance not unlike that of the crest of a dragoon's helmet. The dimensions of the horn were, over its greatest convexity 9.5 centimetres; its diameter at base 3.5 centimetres; and diameter at the point 2.5 centimetres. Its color varied from yellow-ish-brown to black, and its hardness was that of a nail. The horn was removed, with its lateral attachments.

On examination in its long axis, the horn seemed to be composed of fibrillated layers, more densely packed or pressed together upon the outer or external, than at the central portions. On microscopical examination, the horn was found to be composed of compressed epidermic cells. In longitudinal section these were seen to be imbricated like roofing tiles; on cross section, they presented a concentric arrangement.

In the lower third of the great horn, in the spaces between the horn cells, bloodvessels existed; and at the base the horn-plates were continuous with normal epidermis.

CASE XIV.—Mr. Pearce Gould (*Br. Med. Journ.*, Feb. 19, 1877, p. 305) exhibited a specimen of horny growth on the penis to the Clinical Society of London. The patient, aged fifty, had had congenital phimosis. "He first experienced difficulty in micturition about four years earlier, and was circumcised; the wound healed, except in the middle line, where a small granulating surface remained; in connection with this surface, two small warts developed, from the earliest formed a discharge commenced, and continued up to the time he came under Mr. Gould's care. On the middle of the upper surface of the gland was a sessile truncated horn, of yellowish color, translucent, and of the size of a small marble. The penis was amputated, the inguinal glands removed, and the patient rapidly recovered. Microscopic sections of the horn, prepared by Mr. L. Hudson, showed the usual epidermal structure, the cells being flattened, nucleated, and in regular superposed layers; no enlarged papillæ entered the base of the horn; the ulcer was epithelomatous; the glands showed no secondary deposits. Reference was made to Sir Erasmus Wilson's collection of 90 cases of horns, of which 5 were on the penis, and to the later collection made by Lebert of 109 cases, from various sources, of which 6 were on the penis.

"Mr. Gould also mentioned other cases, and stated that his specimen was the fourteenth recorded case of horn on the penis. Some of the horns had reached a great size; in one recorded by Mr. Jewett, the horn was 3½ inches long, and ¾ of an inch in diameter. In another case, recorded by Pick, the horn was 2½ inches long. In the case recorded by Mr. Gould, the patient was in the habit of paring the horn down. It had been shown that horns originated in three ways: from the interior of sebaceous cysts, which was the most frequent mode; from the matrix of nails, and from some change occurring in warts. Those on the glans penis belonged to the last group. Histologically they fell into two classes: the papillary and flat; the specimen shown was of the latter kind."

CASE XV.—In January, 1887, a man, C. C., aged fifty-three, presented himself at the clinic of the Jefferson Medical College of Philadelphia, during the service of Prof. S. W. Gross, with a horny nodular mass on the dorsum of his penis. Its removal was recommended, and assented to by the patient, who however did not return.

Sir Erasmus Wilson (*Medico-Chirurgical Transactions*, 1884, vol. xxvii. p. 64), refers to a paper by Mr. Lozes (*Mem. de l'Academie Royale de Médicine*, June, 1830), in which are reported three cases of horny growths on the glans penis.

Sir Erasmus adds, "In pursuing this inquiry, I have succeeded in collecting 90 cases, of which 5 were on the glans penis." These are most probably included in the foregoing list.

The following cases of horn upon the scrotum may also be referred to.

Lebert and Curling (*op. cit.*, p. 50) (Testis, 1856, p. 503) refer to a specimen of cancer scroti, with a horn-like growth, ¼ of an inch in length, which was removed from a chimney-sweeper, and is preserved in the Museum of the College of Surgeons (No. 2469). The process, when very long, is occasionally twisted like the horn of a ram. Some curious excrescences of this kind are represented in the clever etchings of Mr. Wadd (Cases of Diseased Prepuce and Scrotum. Pl. x. xi. xii.).

THE RARER FORM OF PULMONARY CONSUMPTION.

BY THOMAS J. MAYS, M.D.,
PROFESSOR (ADJUNCT) OF THE CHEST IN THE PHILADELPHIA POLYCLINIC.

To anyone who has had a large experience among consumptives it is quite evident that all such patients may be divided into two distinct classes. To the first, and by far the largest class, belong those in whom the disease is local; or, in other words, those in whom the disease is primarily confined to the pulmonary organs, and the constitution is secondarily affected. The second class comprises those cases in which the disease consists primarily in a constitutional disintegration, and the lungs become involved secondarily.

It is not only necessary that these two classes should be separated from a pathological point of view, but it will also be found that the prognosis as well as the appropriate treatment for each class varies greatly.

The first class comprises those cases in which the disease is in most instances acquired; and the second those in which, so far as my experience goes, there is a strong inherited tendency to the disease, and those who have been delicate during their whole lifetime. The first class may be called a class of walking patients, for, as a rule, they are able to be up and about until within a comparatively short time before their death; while the second class of patients, which in most instances belong to the female sex,

are generally bedfast during the whole or at least during the later period of their affliction.

The preliminary diseases from which the second class usually suffer are malaria, uterine and ovarian disease, neuralgia, anæmia, etc., all of which probably depending indirectly, if not directly, on an impoverished condition of the blood and of the tissues. Again, in the second class, and contrary to what one would be led to expect from the general emaciation of the body, there is usually such a small amount of lung lesion present that the practitioner is frequently thrown off his guard and led to mistake the true nature of the trouble. It is well enough to be cautious in the diagnosis of phthisis when only a slight amount of lung structure is involved, but when we are confronted by a patient who gives a family history which is decidedly tainted with consumption or scrofula, who has only a slight cough, but is thin, has occasional night-sweats, a variable or a complete loss of appetite, is suffering from occasional amenorrhœa, or irregularity of the menstrual flow; who probably made an imperfect recovery from her last childbirth, and in consequence of which she is afflicted with occasional pelvic pains, and especially if, under these circumstances, she is one of the youngest of her parents' family, it is doubly important to be careful in pronouncing an opinion as to the non-phthisical nature of the case, although the physical signs may show nothing more than the distribution of a few moist *râles* throughout the lungs.

In order to make the difference between these two classes of cases more clear I will give an example of the first before presenting one of the second class.

Case I.—J. B., aged forty, carpenter, has been coughing for nearly three years, expectoration is of a yellowish-green color and very profuse, especially in the morning, has had hæmoptysis, is losing flesh, has night-sweats, appetite variable, though usually good, tongue clean, never had malaria or rheumatism, and his evening temperature is 99°. Physical examination shows very little bodily wasting, impaired movement of left chest with slight flattening below clavicle of same side. Tympanic, dull sound on percussion over left apex in front, and dulness behind in same apex. Blowing respiration with creaking and crepitant *râles* in same region, some mucous *râles* distributed from here down to base. Right side normal. Diagnosis: Cavity surrounded by consolidation in left apex. This patient was placed under the external application of hot poultices, massage, inhalation of compressed and medicated air, together with hypophosphites, cod-liver oil, nutritious food, an open-air life, and in the course of two and one-half months there were audible no other abnormal physical signs in left apex than the cavity respiration, and a slight percussion dulness.

The following is the history of a patient belonging to the second class, or to the rarer form of pulmonary consumption:

Case II.—Mrs. X., aged twenty-six, married four years, came under my professional care in June, 1886, at which time she complained of having a cold. The preceding December she gave birth to a boy, which was followed by rather intense abdominal pain, chiefly located in the right ovarian region. A month later she became hot and chilly, and subject to occasional night-sweats; she was losing flesh, and had some cough, but very little expectoration—the latter being light in color. She had no hæmoptysis before this time or afterward. She was very anæmic. Her appetite was poor, and her bowels irregular. Her menses returned for the first time since her confinement, the previous May. She had never been subject to rheumatism, but complained of an ill-defined pain through the body which had a special affinity for the right side of the head behind the ear. Examination of the uterus by an expert gynecologist showed that the pelvic organs were comparatively normal. She lost a brother from pulmonary consumption, and her father had hæmoptysis in his younger days, although he is quite well at present.

Physical examination showed not only a marked degree of emaciation of the chest, but also of the whole body. Impaired respiratory motion over the whole chest. Slight subcrepitation and an occasional click toward the end of inspiration, as well as prolonged expiration in left apex. No dulness, and the right lung normal. Temperature also normal.

At this time she received quinine, iron, strychnine, and atropine, and carbolic acid with respirator. In regard to food she was ordered to take a glass of milk every hour or two, eggs and beefsteak as much as she can possibly eat. A month later she had improved in appetite and in strength, had less cough and expectoration, and night-sweats had diminished. Menstruation occurred at the regular time. *Physical signs:* no *râles*, or clicks, and the prolonged expiration in left apex was the only remaining abnormal sound. In addition to the above-named treatment, I gave her oxygen and compressed air inhalations. She continued to improved in every respect, so far as rational signs could tell, but in the following August her menses disappeared never to return. In two weeks after the cessation of her menses she began to experience severe ovarian pain in the right side, which radiated upward and occasionally gave her intense gastralgia, vomiting, and diarrhœa. At or shortly before this time her chest signs, with the exception of a weakened respiration, were normal. Her temperature was also normal. She had a tolerable good appetite, and the night-sweats were very infrequent. For the ovarian difficulty she was treated by a specialist, but no medication succeeded in permanently relieving the pain.

Saw her again the last week in the following November, when she appeared somewhat worse. The pain recurred at more frequent intervals, and was reflected from her spine over the anterior right side of her chest wall. At this time, the physical signs were principally on the right side of her chest; some dulness in right apex, and blowing inspiration and expiration in both apices. Some coarse mucous râles in right apex, extending to third rib in front, and to apex of scapula behind. A few clicks in left apex. Morning temperature 101° Fah. We now began to poultice her whole chest. There was a strong sympathetic connection between the pain in the chest, and that in the ovary; when it existed in

the former region, it was absent in the latter, and *vice versa*. She often said that the application of the poultice relieved the pain in the chest, but gave her occasionally a temporary pain in the right ovarian region. And strange to say, in proportion as the rational signs disappeared in the chest, the pain in the ovary became worse. I also applied the constant current at this time, which seemed to be the only thing which had the power of giving her any promise of permanent relief from the pain. Indeed, its action in relieving both ovarian pain, and that in the chest wall, was frequently instantaneous, and I feel quite certain that it spared her from a great deal of suffering. Her temperature now became very capricious, and irregular. It was normal, or quite so, for a number of days in succession, and then rose at once to 100° and 101°.

She went home in the middle of last January, when her chest was free from râles, but the dulness had not subsided, and I did not see her again until the middle of the following March, when I found her decidedly worse. She coughed very much, and expectorated profusely. She had a poor appetite, night sweats, and a temperature of 101° and 102° Fahr., morning and evening respectively. The physical signs at this time were as follows: Dulness in both apices. Bronchial respiration in right apex, mucous and subcrepitant râles distributed over the whole lung, as well as some mucous râles in left lung. Sensation and motion were normal throughout the whole body. I now, in addition to the other treatment, began the administration of sulphuretted hydrogen gas, according to Dr. Bergeon's method, twice a day. She thought that the gas relieved her cough and expectoration somewhat, but she was evidently beyond human aid, and died at the close of March.

This case is interesting from more than one point of view. Most deaths from chronic phthisis are caused by an extensive waste of lung tissue; but in this case there was no destruction of lung tissue; no cavity, and hence only a moderate amount of interference with the process of blood-aëration, insufficient of itself to produce death. Unquestionably, however, the disease in the lungs would have gone on to excavation, had she had vitality enough to live longer, under these circumstances; but at the time when the pulmonary organs became definitely involved, her constitution was already shattered to such a degree that there was nothing left to offer any decided resistance to the ingress of the disease, and she died from sheer constitutional exhaustion.

It also teaches an important lesson in regard to the line of treatment which ought to be followed, not only in such, but in all other cases of pulmonary consumption. As has already been intimated, it shows the powerful influence which the constitution sways over the destiny of the consumptive patient. Had the efforts to restore her general condition been successful, there can be no doubt that the case would have terminated favorably, for at no time up to within two months of her death, and probably later yet, was there sufficient pulmonary trouble, considered by itself, to give cause for serious apprehension. Hence, in these cases especially—although we must never lose sight of the great importance of local medication—the constitutional treatment is paramount to everything else. To attain this end, there can be no doubt that good nutritious food is the great desideratum, and all treatment must be subordinate to this aim in these cases. Food must be supplied regularly, and in such a way that the patient does not realize that he is in any manner forced to eat. All consumptives eat best when they are surprised by new foods. Variety gives them a relish which a monotony of dishes could not possibly excite. When the appetite flags give tonics such as nux vomica, tinct. of iron, hypophosphites, quinine, etc. Nothing that offers the least hope of doing good to these patients should be left undone. Change of air and of scenery, forced feeding, and when the anæmia is extreme, the subcutaneous injection of defibrinated human blood, as successfully practised by Prof. von Ziemssen and others, all suggest themselves as being of the greatest advantage in this special class of cases.

A STUDY OF THE PHENYL-HYDRAZIN TEST FOR SUGAR IN URINE, AS APPLIED BY ULTZMANN.

BY A. K. BOND, M.D.,
OF BALTIMORE, MD.

Although the determination of the presence or absence of grape sugar in urine is, as a rule, easy, yet we find now and then cases in which it is extremely difficult to decide by means of the ordinary tests whether the results which we obtain are caused by grape sugar or not.

The fermentation test and the polariscope are unreliable where the percentage of sugar is very small. The reduction tests, the best of which is that of Fehling, are reliable in all cases as *negative* tests—when no reduction is effected no sugar is present; but, as *positive* tests, they fail when the amount of sugar is very small, for, in this case, the results may be due to other reducing substances in the urine. It is with pleasure, therefore, that we read of the introduction of a test of an entirely different order which promises to be a certain *positive* test for sugar in the urine. I refer to the phenyl-hydrazin chloride test, which was introduced by Emil Fischer,[1] and has been applied to the examination of pathological urine by P. Grocco,[2] and by R. von Jaksch.[3]

In the phenyl-hydrazin chloride test the sugar itself is obtained in a crystalline compound, the formula of which is $C_{18}H_{22}N_4O_4$. This compound, which Fischer names phenyl-gluko-azon, appears in the form of a yellow sediment which, under the microscope, is seen to consist of fine yellow needles. According to Fischer phenyl-glukosazon is not affected by watery solutions of alkalies. Suspended in warm water, it reduces alkaline copper solutions energetically. It dissolves in hot alcohol, and crystallizes out, when water is added, in the form of yellow needles. Heated to 204° C., it melts to a

[3] Mittheilungen des Wiener Med. Doctoren-Collegiums, 10 Band; See also, his book, Klinische Diagnostik Innerer Krankheiten

dark red liquid, and at a higher temperature it is decomposed. Crystals, resembling those formed by glucose, are obtained from other members of the sugar group—levulose, galactose, sorbin, milk sugar, and maltose—but I find[1] that of these only levulose and milk sugar are ever found in the urine. Levulose is found only when dextrose is present, and milk sugar only during the course of the so-called milk fever. All observers agree that these sugars are the only substances which, under the conditions present, yield such crystals. The studies of Fischer, Grocco, and Jaksch have made this test an extremely valuable one in the hands of skilled investigators and chemists, but the addition of water to the urine interferes with the exactness of the results, and the use of the water-bath is quite unnecessary.

It is my purpose in this paper to describe a simple and rapid mode of using this test, which I learned from Professor Robert Ultzmann at his clinical lectures in Vienna, in the winter of 1885–86. I do not think that Dr. Ultzmann has yet published anything upon the subject, but the matter is of such importance that I do not hesitate to quote his words.

My notes upon his lectures are as follows: "It is a very simple test, and the most exact of all. Put into a test tube 1 cm. high of the phenyl-hydrazin chloride, and upon it 1 cm. (a little less than this) of crystals of sodium acetate. Then add urine to the half-test tube. Boil the mixture till it becomes clear. Let it stand for fifteen minutes, and examine the sediment for crystals. If albumen is present, you must first coagulate and filter. The urine must be clear. If there is no sugar, we find no such crystals. These crystals are in yellow sheaves, unlike any other product which appears in urine. Tyrosin gives crystals of a somewhat similar shape, but they are not yellow, and appear in urine only on rare occasions, as in acute yellow atrophy of the liver. This tyrosin, too, is a natural, not an artificial, product. Leucin, which has at times a somewhat similar shape, is unlike in color.

"This method is also useful for determining approximately the *quantity* of sugar in the urine."

Here, then, was a method which seemed in simplicity and accuracy to be exactly what is needed for the practising physician's use.

I procured some of the phenyl-hydrazin chloride in Vienna, and since my return from Europe I have made a very careful study of the test as applied by Ultzmann (for convenience, I shall speak of it as "Ultzmann's method"). The result is that I fully endorse his recommendation of it, although, in some respects, my experience has been different from his.

In my experiments I have used no appliances save those which are within the reach of every physician. Yet, in determining the sensitiveness of the test, I have exercised the greatest care in the preparation and measurement of my standard solutions of sugar.

I make the test as follows: I pour the phenyl salt—which is a dry substance resembling bran—into an empty test-tube until the tube is filled to the distance of about four-tenths of an inch from the bottom, and add crystals of sodium acetate, ground fine, to an equal height. Upon this I pour the urine—clear or cloudy—until the tube is half full. This gives in a test-tube five inches long, about the following proportions in weight: 1 part phenyl salt, 2 parts sodium acetate, 15 parts urine. I shake the tube until the crystals of sodium acetate are dissolved, then heat gently over a low flame until the mixture boils, and boil it for about half a minute—whether it becomes clear or not makes no difference. I then cover the tube and let it stand, and, after a proper interval, examine the sediment with the microscope. If sugar is present there will be seen first fine, bright yellow needles, which branch out or are joined by others as they are formed, until the field is dotted with groups like delicate sprays or sheaves, or radiating from a centre. A magnifying power of 200 diameters is sufficient for this study. That the phenyl salt is always in excess when the test is made in this way is shown by the constant presence of reddish globules in the field.

My experiments fall naturally into two series. The first series includes those made for the purpose of finding how long the mixture must stand before the crystals appear; of determining what percentage of sugar is necessary for the formation of the crystals; and of comparing this test, as simplified, with Fehling's test, which I believe to be the best heretofore in use. For this series I used, instead of pure grape sugar, which cannot easily be weighed, a crystalline compound of sodium chloride and grape sugar, which is easily weighed. A solution of this salt in distilled water (containing, by calculation, 1 part of anhydrous glucose to 1250 of water) gave, by Ultzmann's method, after standing eighteen minutes, a sediment in which, by the aid of the microscope, the crystals could be seen grouping themselves into delicate, spray-like forms. The same mixture yielded, twenty-one hours later, a yellow sediment, which was seen, with a one-inch objective as a hand-lens, to consist of feather-like groups of yellow, needle-shaped crystals. Under the microscope abundant sheaves of yellow crystals were seen. A mixture containing 1 part of sugar to 2000 parts of normal urine, which gave a fair reaction for sugar by Fehling's test, yielded, by Ultzmann's method, on standing twenty-two hours, four or five large yellow sheaves to a field of the microscope, and after it had stood forty-eight hours, about a dozen sheaves to a field. Mixtures containing 1 part sugar to 3000 or 4000 parts normal urine, which gave, with Fehling's fluid, very uncertain tests, yielded, by Ultzmann's method, after twenty-two hours, no crystals; but twenty-three hours later, several well-formed sheaves to a slide. It is possible that still more dilute solutions of sugar in urine might yield the crystals when treated in this way, but for ordinary office-use greater accuracy than this is not needed.

The second series includes those experiments made to determine whether, under any circumstances, the test, as applied by Ultzmann, fails to give the crystals in urine which contains more than one-fortieth per cent.—1 part to 4000 parts—of

[1] Neubauer und Vogel, Analyse des Harns, 1881.

grape sugar. In these experiments I used solutions of known strength of very pure grape sugar in distilled water. I treated by Ultzmann's method in all fourteen mixtures of these standard solutions with fresh, non-saccharine urine containing from one-thirty-sixth to one-half per cent. grape sugar, and obtained the yellow crystals in every case. In eleven of them the crystals appeared within twenty-four hours after the test was made; in three of them when the mixtures had stood more than twenty-four hours. Several of these fourteen mixtures were made with urine which threw down phosphates on boiling; one with urine which yielded, on standing before tested, a very abundant sediment of urates; one with urine containing a considerable quantity of albumen—the yellow crystals in this case in part appearing in the masses of coagulum, in part settling from the supernatant fluid in the form of sheaves; one with urine to which I had added quite an excess of sodium bicarbonate, to find whether alkalinity of the urine interferes with the test—in this case brisk effervescence occurred from the action of the bicarbonate upon the phenyl salt, but, as the latter was in excess, the solution continued acid and the crystals appeared, though in smaller numbers than usual.

These tests with artificial solutions of glucose in urine were confirmed by similar tests with the urine of patients suffering from diabetes mellitus.

Many tests were made with normal urine, but in none of them could I find even a single yellow crystal or sheaf.

Through the kindness of a medical friend, I had the opportunity of testing, by Ultzmann's method, a very interesting specimen of urine[1] which contains a substance which was mistaken for sugar by several life insurance examiners. This urine behaved with the phenyl-hydrazin test exactly like normal urine.

In the sediment from a solution of sugar in hydrant water, tested by Ultzmann's method, a yellow plant was found under the microscope, which in its very earliest stages resembled somewhat in color and form small sprays of sugar crystals. Upon further observation, however, the peculiar manner of growth of the plant removed all doubt upon the subject. This plant was not found in any of the urine mixtures.

I will now state briefly the results of my work:

The test of Fischer, as applied by Ultzmann, is easy to make, and does not take more time than Fehling's test, if, as is necessary, the latter be made with fresh solutions.

It is suitable for office use by physicians, and may be accurately made by those whose training in chemistry is imperfect.

It does not require great skill in the use of the microscope. In all my examinations the crystals, if present, were found upon the first slide examined.

When the sugar present amounts to one-fifteenth per cent., the crystals may be found fifteen minutes after the test is made.

The test is about as sensitive in the presence of sugar as that of Fehling, and is not liable to be disturbed by other substances contained in the urine. It is obtained in alkaline as well as in acid, in cloudy as well as in clear urine.

Normal urine does not respond to the test.

If the crystals are found, the proof of the presence of sugar is absolute.

My experiments lead me to believe that in *all* cases in which sugar is present in the urine to the amount of one-fortieth per cent. or more, the crystals may be found—although it may be necessary, when the quantity of sugar is very small, to let the mixture stand after boiling as many as forty-eight hours.

The single crystals show a strong tendency, in the most dilute as well as the most concentrated solutions of sugar, to form clusters; so that, in solutions which have stood some time, only the characteristic clusters may be found.

The crystals or clusters undergo no change of importance in aqueous solutions for a month or more, and so any sediment may be preserved and inspected from time to time. Even in urine mixtures they remain for weeks unchanged, decomposition of the mixtures being prevented by the phenyl salt.

Ultzmann's method may be used for rough *quantitative* determinations. In case the urine contains one-tenth per cent. or more of sugar, we may estimate the amount from the quantity of yellow crystalline sediment, even when the urine is not clear. When less than one-tenth per cent. is present, the amount may be roughly estimated from the number of crystals in a field of the microscope.

The salt of phenyl-hydrazin used for the test is quite stable, retaining its properties for months (apparently for years), even when exposed frequently to the air.[1]

[1] Described by Dr. Bruen, Boston Med. and Surg. Journal, December 30, 1886, and January 27, 1887; and by Dr. Marshall, THE MEDICAL NEWS, January 8, 1887.

A CASE OF VENOUS ANASTOMOSIS ON THE DISK.

BY CHARLES W. KOLLOCK, M.D.,
OF CHARLESTON, SOUTH CAROLINA.

CASES of this kind are rarely seen, and the only one of which I have seen a report is that of Dr. B. Alexander Randall, in THE MEDICAL NEWS of September 11, 1886.

This anomaly occurred in the right eye of Miss A. B. The disk shows no signs of inflammation, but at the upper border of the disk a distinct connecting branch is seen between the superior nasal and temporal branches of the retinal vein. The patient has had trouble for years with her eyes, owing to errors of refraction and granular lids. Her general health has also been poor, and she is at present quite anæmic. With the following correction she sees $\frac{20}{xx}$. R. —0.75c. 30° ⊂ + 0.75c. 120°. L. — 0.50D.

A choroidal ring, more distinct on the nasal side, surrounds the disk.

MEDICAL PROGRESS.

The Physiology of Bergeon's Enemata.—At a recent meeting of the French Academy of Sciences, Bergeon read a communication in which he stated that carbon dioxide when introduced into the intestine was eliminated by the lungs in a manner similar to the diuresis of fluid through the kidneys. He stated that the tissues thus become impregnated with it. Pure gas was eliminated by the lungs; impure gas remained in the intestine, causing distention and colic.—*Gazette Hebdomadaire*, No. 26.

Total Extirpation of the Cancerous Uterus.—Dr. Fritsch has recently published in the *Archiv für Gynäkologie* a communication on sixty cases of removal of the uterus through the vagina for cancer, the condition for which alone the operation is indicated. 7 out of the 60 patients died after the operation, a mortality of 11.6 per cent. 2 died from hemorrhage, 1 after syringing the vagina, 3 from peritonitis, and 1 from ligature of the left ureter. In the last case the kidneys were contracted. Of the 53 survivors from the operation, 17 had died already from recurrence, in 6 still living recurrence was reported by competent observers, 3 patients had not been heard of since their discharge, and 3 were only operated upon in September and October, 1886. 24 remained in good health, 9 of these being reckoned as cured, two years having passed without recurrence.

Dr. Fritsch does not agree with Ruge that three distinct forms of uterine cancer exist—cancer of the body, cancer of the canal of the cervix, and cancer of the surface of the vaginal portion. The last two forms are not always to be distinguished from each other. In both, Dr. Fritsch observes, the disease always begins on the boundary line between the squamous and the cylindrical epithelium. It is more important to divide cervical cancer into the exuberant or hypertrophic fungating form of the exedent, or rapidly ulcerating type.

Dr. Fritsch objects to supra-vaginal amputation of the cervix; first, because in some cases of cervical cancer nodules have been found in the fundus; secondly, because the operation is liable to be followed by severe atresia; and, lastly, because hemorrhage cannot be so readily controlled as during total extirpation. The operation, Dr. Fritsch observes, should only be performed when a permanent one appears probable. The uterus must be freely movable. When its mobility is impaired, cancerous deposit in Douglas's pouch or in the broad ligaments will almost certainly be discovered. The fungous type is the least serious, provided that the vaginal mucous membrane is not involved. On the other hand, in cancer hardly visible at the os externum, the parametric tissue is often extensively infiltrated. Dr. Fritsch is opposed to preliminary scooping out of diseased tissues or other partial operations, which, in his opinion, disturb the lymphatics and promote the spread of the disease.

With regard to the stages of the operation, as performed by Dr. Fritsch, his principle is to keep the peritoneum open for as short a period as possible, and not to lay it open till the most difficult steps have been performed, and to get the uterus as freely movable as possible by detachment of broad ligaments from their lateral inferior connections, so that the operator may know in time if really total removal of the growth is possible. Should the parametric tissues be found to be involved, the surgeon must proceed no further. Dr. Fritsch neither sews up the flaps nor drains; he plugs the vagina with iodoform. The greatest difficulties are encountered when the uterus is large. Dr. Fritsch has in these cases combined abdominal section with the vaginal operation. He does not believe that the patient need lie in any particular position after operation; the scanty secretion from the wound can be removed by pledgets of iodoform gauze. After recovery, a smooth and straight scar in the vault of the vagina is more favorable than a hard funnel-shaped cicatrix. No doubt, timely performance of total amputation of the uterus through the vagina promises the best results, as uterine cancer does not appear to recur rapidly when completely removed. The operation, however, is difficult and tedious even for experts.—*British Medical Journal*, June 25, 1887.

Spartëine, a Heart Stimulant.—Langgaard reports the following formulæ, which he found useful in eighteen cases of heart diseases:

℞.—Spartëin. sulph. . . . . gr. 6.
Pulv. rad. liquirit.
Succ. liquiritæ . . . . . ää q. s.
Ft. pil. 20 in num.
Sig.—One or two pills from two to four times daily.

Also

℞.—Spartëin. sulph. : . gr. 3 to gr. 7.
Aq. destill. . . . ʒ 2½.
Solve.
Sig.—Twenty drops, from two to four times daily, in sweetened water or wine.

℞.—Spartëin. sulph. . . gr. 3 to gr. 7.
Syr. aurant. cort. . . ʒ 12½.
Solve.
Sig.—A small teaspoonful in water, from two to four times daily.—*Therapeutische Monatshefte*, June, 1887.

The Use of Cocaine in Hay Fever.—Sir Andrew Clark describes his method in the *Lancet* of June 11, 1887, as follows: "There are three ways of using cocaine in the local treatment of hay fever: it may be used in the form of a solution, of a spray, or of a nasal bougie. Personally, I prefer to use a solution varying in strength from five to fifteen per cent., and I apply it to the interior of the nose and the back of the soft palate by means of a large camel-hair pencil attached to an aluminium shank, and bent at an appropriate angle. For use in the form of nasal bougies, a quarter of a grain or more of the hydrochlorate of cocaine is dissolved in a mixture of gelatine and glycerine, and made of different weights and shapes, according to the peculiarities of the case on which they are to be employed. For using cocaine in the form of spray, some efficient and ingenious spray producers have been invented. Many of them are furnished with nozzle so constructed that the spray can be applied directly to almost any part of the nasal and pharyngeal cavities. These spray producers, with weak cocaine solutions, are sometimes very useful in allaying the small but still troublesome irritation

which, in the intervals of the hay-fever paroxysms, are apt to arise in the eyes and mouth."

THE EUCALYPTOL TREATMENT OF PULMONARY TUBERCULOSIS.—At a recent meeting of the Academy of Medicine of Paris BALL reported 21 cases treated by hypodermatic injections of eucalyptol; 6 died, 10 were much improved and left the hospital, 5 remained under treatment. The influence of the drug was the lessening of night-sweats, diarrhœa, expectoration, and fever; and tubercle bacilli disappeared.

DUJARDIN-BEAUMETZ reported that in his hands the remedy lessened expectoration, but did not influence the bacilli.

GUIFFERT, of Cherbourg, had treated 5 cases with marked general improvement. He mentioned 2 cases which Bergeon's treatment failed to benefit, which the treatment under discussion greatly relieved.—*L'Union Médicale*, June 11, 1887.

THE TREATMENT OF HEPATIC CONGESTION.—JULES CYR is quoted by the *Revue de Thérapeutique*, of June 15, 1887, as using the following treatment:

1. Application over the liver of compresses of cold water, often renewed; two or three leeches about the anus.

2. At evening, three-fourths of a grain of calomel should be taken, followed the next morning by five drachms of Glauber's salts.

3. As beverage, milk and Vichy water, or seventy-five grains of ammonium chloride in a quart of water.

4. A douche, while the patient is reclining, of water at a pleasant temperature, given over the hepatic region.

THE TREATMENT OF HÆMOPTYSIS.—From an extensive article by BARIÉ, in the *Revue Générale de Clinique et de Thérapeutique* of June 16, 1887, we take the following useful formulæ:

Tannin is a remedy most frequently used; its dose is from 9 to 15 grains; or by tablespoonful doses of the following:

R.—Tannin	gr. 8 to gr. 15.
Tinct. cinnamon.	♏. 30.
Syrup. simp.	ʒ ½.
Aquæ aurant. fl.	ʒ5.
Aquæ	ʒ25.

If gallic acid be preferred to tannin, it may be combined with ergotin as follows:

R.—Acid. gallic.	gr. 30.
Ergotin	gr. 15.
Glycerin.	gtt. 5.
Syrup.	q. s.

Make 20 pills.

5 pills should be taken daily. In cases where the use of krameria or ratanhia with ergot and digitalis is indicated, the following will be found useful:

R.—Ext. ratanhiæ	ʒ1.
Ergot.	gr. 45.
Digitalis pulv.	gr. 8.

To be made into 40 pills, of which 6 may be taken daily.

THE FREQUENT OCCURRENCE OF DISEASE GERMS IN THE HUMAN BODY.—In discussing the investigation of scarlatinal infection now in progress in England CROOKSHANK remarks as follows in the *Lancet* of June 25, 1887:

"We must bear in mind, in connection with this subject, that saprophytic organisms may occur in man, both in health and in disease, which produce very characteristic symptoms in the lower animals.

"If they gain access to the circulation through some surface lesion, they may, in an advanced state of disease especially, escape disintegration and be detected in the blood and in the organs after death. Thus they may readily be mistaken for the specific organism, if there be one, of the disease in question. We may also find more than one organism associated with a disease as the result of a double infection. Kassowitz and Hochsinger found in the organs of children which had died of congenital syphilis streptococci, which were regarded as the result of *Mischinfection*. It is interesting also to recollect how commonly streptococci have been met with. In addition to those I have already mentioned, we must bear in mind the streptococci in purulent inflammations found by Ogston, Rosenbach, Krause, Garrè, Hoffa, and Biondi, the streptococci found by Weichselbaum in acute pneumonia, the streptococcus isolated by Nicolaier from earth, the streptococci found by Emmerich in the air, and, I may add, the streptococci found by Babes in the liver and kidney in two cases of yellow fever; in the liver, kidney, and spleen in a case of *fièvre typhoide bilieuse*, and in inflammatory products consecutive to scarlatina, by Bokai and by Babes in joint affections after scarlatina, and by Charrin in septicæmia consecutive to anthrax in rabbits. In conclusion it is obvious that the experiments which have been analyzed must be repeated and extended before a definite opinion can be expressed: and as in addition to its pathological interest the inquiry involves a question of national importance, it is to be hoped that a commission will be appointed. By testing the result of inoculating blood from human scarlatina direct into the calf and the monkey, and by repeating and extending the experiments of Dr. Klein and Dr. Edington, there ought to be no difficulty in dispelling the present contradictions."

MILK DIET AND THE EXCRETION OF UREA.—CHIBRET reported to the French Academy of Sciences the results of a series of observations of persons upon milk diet, as follows: Examination by means of sodium hypobromite, of the urine of such persons, showed a great increase in the amount of urea excreted; the diet had been rigorously followed two months. The urine of a person in health was compared with that of two patients upon milk diet by means of diagrammatic curves; it was found that a solely milk diet increased the excretion of urea from sixty to one hundred per cent.; when milk formed only a part of the diet the percentage of urea was thirty-five. As one of the patients, who was obese, lost flesh, while the other, who was thin, gained flesh upon this diet, it is evident that the increased excretion of urea was not caused by denutrition.

The increase and loss of flesh corresponded to the variations in fat and glycogen in the two patients, and not to any variations in urea.—*Revue de Thérapeutique*, July 1, 1887.

Cocaine and Atropia for Iritis.—Guiaita gives the following as used by many ophthalmologists:

R.—Cocain. hydrochlor.	gr. 3.
Atrop. sulphat.	gr. ¾.
Acid. boric.	gr. 4.
Aquæ destillat.	ʒ2½.

—*L'Union Médicale*, June 25, 1887.

The Treatment of Morphia-craving by Sparteine and Nitro-glycerine.—Dr. Jennings, of Paris, writes to the *Lancet* of June 25, 1887, an article on this subject whose conclusions are as follows:

"To sum up, the morphia-craving is a complex suffering, at the same time cerebral and peripheral, each factor of which can be relieved by appropriate treatment. The organic distress may be soothed by sparteine, which recovers the heart in the same way as a hypodermatic injection of morphia. The cerebral craving (or yearning), often the more painful of the two, corresponds to a want of habitual congestion. This can be arrested with nitro-glycerine, which gives rise to the same kind of sensation in the morphia *habitue* deprived of his stimulant as the hypodermatic injection. It acts probably by inhibition *à distance* rather than by essential sedation of the nervous centres."

Preputial Calculi.—From the *Indian Medical Gazette* of April, 1887, we take the following account of an unusual case:

A ryot of Myoor, æt. forty-five, came to the Chingleput Dispensary to be relieved of difficulty in passing his urine.

He stated that his troubles began about four years ago, with phimosis, and, being unattended to, the preputial orifice gradually became smaller, with increasing difficulty in micturition.

The urine collected within the prepuce, distended it into a bag, and had to be squeezed out through the minute orifice, which did not admit the probe easily. On handling the prepuce, urinary calculi could be felt rubbing against each other. The penis was about one and a half inches longer than normal, curved somewhat downward; and the calculi were felt in front of the glands. The prepuce being slit up, three large calculi dropped out, of the size of average carpal bones. They were moulded to the shape of the preputial cavity, and were marked by facets.

He was discharged cured in five days.

The noteworthy circumstances in this case are the large size of the calculi, their unusual location, and the length of time that had been allowed to elapse before relief was sought. They were to all appearance phosphatic.

Mercurial Injections.—A discussion has recently been taking place in the Brussels Medical and Scientific Society as to the relative advantages of mercurial injections and inunctions combined with internal medication. Dr. Thiry prefers the latter method, as he thinks injections are attended with serious risks and inconveniences. M. Ed. de Smeth, on the other hand, practises injections largely—in fact, always—when mercury is indicated in syphilitic patients. At present there are in his wards 24 such cases in which no less than 900 injections have been given without any accident occurring; and M. de Smeth thinks that, as, apart from his own practice, M. Martineau has reported a series of 180,000 injections without any accident, Lewin 300,000 with 20 abscesses, and Paikert 5000 without any, it cannot be said that this form of treatment is more liable to inconveniences than other forms. He points out that there is a great difference between injecting insoluble salts, as calomel and the yellow oxide, in the way recommended by Scarienzo, upon which method M. Thiry's experience of injections was mainly gained, and injecting soluble salts, which is the plan he himself prefers and follows. Here, he says, the only objection to the injections is that the patient must be regularly seen by the doctor, which in private practice is sometimes inconvenient. Of course care must be taken that the syringe is perfectly clean and that the liquid is well filtered. In order to illustrate the occasional importance of the rapid action which can only be obtained by the method of injecting soluble salts of mercury, M. de Smeth mentions a case of syphilitic laryngitis of so urgent a character that it was thought that laryngotomy would be needed. However, by means of hypodermatic injections repeated five or six times during the course of twenty-four hours all danger was averted.—*Lancet*, June 25, 1887.

The Treatment of Eczema occurring at the Crises of Life.—Chéron advises the following treatment, in the *Revue de Thérapeutique* for June 1, 1887:

1. At each meal a teaspoonful of the following:

R.—Sodii arseniat.	gr. ¼.
Aquæ destill.	ʒ 4¾.

2. Constipation should be relieved by a saline purgative, generally citrate of magnesia, taken twice weekly.

3. An application should be made every evening of the following salve, used very gently:

White precipitate	gr. 15.
Vaseline	ʒ 5.
Essence of roses	gtt. 2.

4. Every eight or ten days the following hypodermatic injection should be given:

Nitrate of pilocarpine	gr. 1½.
Aquæ destill.	℥ 75.

An injection of from six to ten drops.

Contra-indicated in disease of the heart or great vessels.

The Effect of Essences upon Bacteria.—In the *Annales de l'Institut Pasteur*, No. 4, April 2, 1887, M. Chamberland examines the action of essences on the bacteria of charbon, and on many other less well-known microbes. The number experimented upon was 115; only fourteen allowed the development of the charbon bacillus in yeast-water saturated with their vapor. Among these was essences of cloves, which is sometimes used to arrest dental caries. But out of 102 essences that by their presence prevent the development of the organism, only eight seem to kill it definitively, for it usually revives as soon as the essences have evaporated. The essence of cinnamon alone appears completely to destroy the germs in four days, whilst bacteridian germs placed in fresh yeast-water

have been cultivated after having been for four days in contact with other essences. Essence of China cinnamon does not stop the development of filamentous bacteria, but essence of vespetro seems to kill it completely in eighteen hours. Placed in contact with carbuncle bacillus or its germs, in solution essence ½ cc., alcohol 10, saponine solution at 1-100th 20, water 70), seven essences kill that bacterium in doses varying from 1-13, 200th, to 1-24, 200th. These essences have about the same antiseptic power as sulphate of copper. Among these seven essences are three of great antiseptic power, either in solution or in vapor; essence of China cinnamon, of Ceylon cinnamon, and of origanum. The essence must be used fresh; when they become oxidized by exposure to air, they lose part of their properties. M. Chamberland next compares the antiseptic action of thymic acid and of different salts upon bacteria. The bichlorides of mercury, and of ammoniac and sulphate of silver, act at a strength of 1-80,000th; after these come thymic acid, persulphate of iron, chloride of zinc, etc. In order to study the antiseptic power of certain substances upon organisms in general, he prepared solutions of these substances at 1-100th, of which he poured 1 cc. into a series of small flasks containing severally 5 cc., 10 cc., and 20 cc. of neutral yeast, which gave him solutions of 1-600th, 1-1100th, and 1-2200th; to each of these he added ½ c. c. of washings of garden soil. He found that the most energetic antiseptics were sublimate of mercury and thymic acid. Sulphate and acetate of copper and bichromate of potash, although very active, allowed vegetations to grow; next to them in power were China cinnamon, persulphate of iron, carbolic acid, alum, and sulphate of quinine. Boric acid, hyposulphite of soda, salicylate of soda, arseniate of potash, bisulphide of soda, chloride of alumina, and chloride of lime are comparatively weak antiseptics.—*British Medical Journal*, June 18, 1887.

THE USE OF TALLOW TO SETTLE URINE EXAMINED FOR ALBUMEN.—MÉHU describes, in the *Annales des Maladies des Organes Génito-Urinaires*, for June, 1887, the following simple expedient:

In testing urine for albumen by hypobromite of sodium, the reaction is often obscured by a volume of nitrogen gas, which causes a film or mist, concealing the reaction obtained. Alcohol was formerly tried, but was inconvenient from the bulk required. A small mass, or pellet, of tallow, if placed in the test-tube before the agent producing the reaction is added, and the fluid shaken once or twice, will prevent the formation of the cloud of gas described. The gases contained in recently evacuated serous fluid may be dissipated by allowing a few drops of tallow from a burning candle to fall into it.

CITRATE OF CAFFEINE IN CARDIAC DISORDERS.—JACCOUD has used the following with benefit as a cardiac stimulant:

R.—Caffeine	. . . . .	gr. 100.
Sodii benzoat.	. . . .	ʒ 2.
Aquæ	. . . . .	ad. ʒ 8.

He prescribes from three to six grains in twenty-four hours; and in severe cases goes to twenty-five grains.

When the remedy is not well borne by the stomach, it may be given hypodermatically, and the following formulæ have been found useful by TANRET:

	Sodii benzoat.	gr. 40.
	Caffeine	gr. 35.
	Aquæ destill. . . .	ad. ʒ 2¾.
Also,		
	Sodii salicylat.	gr. 45.
	Caffeine	ʒ 1.
	Aquæ destillat. . .	ad. ʒ 2¾.

Dosage to be varied with the indications and amount of caffeine required.—*L'Année Médicale*, 1887.

THREE HUNDRED CASES OF OÖPHORECTOMY FOR UTERINE FIBROMATA.—DR. G. ZVORYKIN has collected statistics of nearly 300 cases of spaying (*kastratsia*) for uterine fibroids. A large proportion of these are from English and American sources; seven, however, are contributed by Russian surgeons, six by Dr. Zvorykin's chief, Professor Lebedeff, and one by Dr. Salmanoff. Two of them are described as interstitial, three as multiple interstitial, one as interstitial cavernous, and one as subserous multiple interstitial. In all these seven cases, both ovaries, and in three of them more or less of the tubes, were removed. The hemorrhage from which all the patients had suffered ceased, and no bad symptoms occurred. Dr. Zvorykin compares spaying with myotomy, and believes the one to be as devoid of danger as the other. Spaying, he considers, is indicated in cavernous fibromata; in retro-cervical or interligamentous tumors, where myotomy would be attended with danger; in all interstitial fibromata, especially in small ones where menorrhagia is the chief symptom; in subserous fibromata of large size, if they give rise to menorrhagia; and in cases where the patient has become so anæmic and weak that the loss of blood necessarily attendant on the operation of myotomy would be likely to affect her condition seriously. Spaying he considers contraindicated in subserous fibroids with long pedicles which can easily be removed; in large interstitial fibroids causing symptoms of weight and bearing down, but unattended with menorrhagia; in fibro-cystic tumors; in young subjects in whom fertility may be restored after myotomy; and, lastly, in cases where the ovaries are enclosed in a mass of false membranes, and their removal is consequently attended with great difficulty.—*Lancet*, June 25, 1887.

HOT-AIR BATHS IN SYPHILIS.—DR. STEPANOFF, of Moscow, has contrived a plan of treating patients suffering from syphilis which has resisted mercurial and iodine treatment. He has had a box or bath constructed with an iron bottom lined with thick felt, in which the patient is placed. The bath is heated to about 170° to 190° F. by means of two Bunsen's lamps, each consisting of five burners. After the patient has been "baked" he is put to bed and covered with blankets, so as to prolong the sweating process commenced in the bath for an extra half-hour. After this he is allowed to dress and go into the ward to his dinner. By means of these baths the mercury is rapidly eliminated from the system and the patient's condition greatly improves, and after a course mercury is found to act quickly and energetically.—*Lancet*, June 25, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1024 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, AUGUST 6, 1887.

PERNICIOUS ANÆMIA.

At the last Kongress für innere Medicin, LICHTHEIM gave his experience concerning the dependence of pernicious anæmia upon the presence of the bothriocephalus latus in the intestinal canal. In the course of the last year he had observed two cases, of which the first presented itself before the publication of Reyher's interesting communication upon the same subject in the *Deutsches Archiv für klin. Medicin*, Bd. xxxix. In the first case, on account of the extreme weakness of the patient, no attempt was made to expel the parasite, or rather parasites, for post-mortem six bothriocephali were found in the intestinal canal. In the second case the parasite was expelled without perceptible effect upon the course of the disease. Lichtheim has seen nine other cases of pernicious anæmia in which no parasite of any kind was found in the digestive tract. He concludes, therefore, that the *rôle* of the bothriocephalus in the production of pernicious anæmia is a modest one, but admits that, clinically and anatomically, it is impossible to distinguish the cases in which the bothriocephalus is present from those in which it is absent.

The same observer also directs attention to the presence of degeneration of the posterior columns of the spinal cord in certain cases of pernicious anæmia. He has observed two such cases in which the diagnosis of tabes was confirmed by the necropsy, and a third in which, although the clinical evidence was not altogether complete, and there was no post-mortem examination, there was reason to suspect the presence of tabes. The affection of the cord is regarded as secondary to the anæmic condition, because the symptoms of the former either follow or are synchronous with those of the latter, and, in addition, the anatomical changes are those of an acute process. This is true also of the symptoms, which manifest themselves in the upper extremity much earlier than in ordinary tabes.

Lichtheim closes his communication with a consideration of the curative value of transfusion of salt solution in pernicious anæmia. He had become convinced that this measure was deleterious, both to the patient and the blood, and had abandoned it, but was induced to resume it by the favorable report of a case by Lépine, with the result of strengthening his former convictions. Of five cases in which he had lately employed it, two died a few days after the operation; two recovered from the operation, their blood condition remaining the same as before; the fifth was not unfavorably affected by the transfusion, soon after which the condition of the blood decidedly improved. The conclusion was that in anæmia of high grade and acute course, transfusion of normal saline solution is contraindicated; while in more chronic cases of lower grade, it may, perhaps, be of benefit.

In the discussion upon Lichtheim's report, JÜRGENSEN referred to a case of profound anæmia in which, the possibility of infection with anchylostomum duodenale not being entirely excluded, he exhibited the extract of male fern. A careful examination of the stools demonstrated the absence of anchylostomum, but showed enormous quantities of bacterium termo—the ordinary bacteria of putrefaction. Immediately after their expulsion improvement set in and proceeded to complete recovery.

LITTEN states that in fourteen cases he had examined the blood and feces without finding any of the parasites described by other observers of this disease. He believes that there are cases of pernicious anæmia for which, as yet, no sufficient cause has been discovered, while there are others, resembling the former in their finest details, which are fully explained by the presence of cancer, by changes in the gastric and intestinal mucosa, etc. This is certainly the most reasonable view of this obscure question, although there appear to be no good grounds for separating the pure cases of pernicious anæmia—*i. e.*, those of which the cause is unknown, from those of which the cause is known. The question is one of blood changes, and they are the same in both. A blood containing megalocytes, poikilocytes, and microcytes is the blood of pernicious anæmia. This condition may be secondary—*i. e.*, the cause is known; or primary—*i. e.*, the cause is, as yet, unknown.

A NEW INDICATION FOR AN ARTIFICIAL VESICO-VAGINAL FISTULA.

An artificial opening from the vagina into the bladder was advised and practised many years ago,

by the late Sir James Y. Simpson, by Emmet, and others, for cystitis. The chief principle upon which this operation was founded was that of giving the diseased organ complete rest; the bladder thus freely opened was no longer tormented by the presence of urine, and hence the spasmodic and painful contractions excited by this secretion ceased, for it escaped through the artificial opening immediately after its entrance. This operation was done in cases of catarrhal cystitis, in which other means faithfully tried had failed to effect a cure.

Pinard and Varnier, in the *Annales de Gynécologie et d'Obstétrique*, sustain the recent proposition of Hartmann, that the bladder should be opened through the vagina in cases of gangrenous cystitis. Such cystitis is most frequently the consequence of retroversion, or retroflexion, of the gravid uterus. It has also been observed to follow in some cases prolonged impaction of the child's head in the pelvic cavity. We might add to these causes an instance under our own observation, in which the accident resulted from a well-nigh mortal vesical hemorrhage which followed dilatation of the urethra with the crushing and removal of a very large calculus.

The indications for the operation, in case the cystitis occurs in consequence of a posterior displacement of the gravid uterus, are thus stated by Pinard and Varnier: When notwithstanding the disappearance of all cause of compression—either by restoration of the displaced organ, or the production of abortion—when, in spite of antiseptic washes, the urine remains opaque, fetid, ammoniacal, and mixed with broken-down membranes; if there is fever with an evening exacerbation, dryness of the tongue, and rapid emaciation; if hæmaturia occurs, and the catheter does not evacuate either urine or injected fluid, the operator should act at once. The only two plans presented are dilatation of the urethra, and opening the bladder through the vagina. But the former does not so readily permit the escape or the removal of the sloughing tissues, while, on the other hand, the latter gives freer access for exploration, and for the extraction of the foreign body, and the use of alterative injections; it also secures drainage and complete rest for the bladder.

The treatment thus advised for gangrenous cystitis we believe to be wise; and we wish that it had been suggested before we met with the only case we have seen of the disease, for though our patient recovered, it was only after a long illness, during a great part of which the result seemed doubtful.

CHOPART'S AMPUTATION.

In our issue of July 16th, Prof. J. B. Murdoch, of Pittsburg, published an interesting address upon Chopart's amputation, and relates certain personal experiences of an exceedingly favorable character. He enters a strong plea for the performance of this operation in suitable cases, in preference to the methods of Syme or Pirogoff. Whilst some surgeons are opposed to Chopart's operation in all cases, and teach that it ought never to be performed, a larger number of equally good authorities recommend the procedure in appropriate cases. Bryant is especially earnest in his advocacy of the operation, whilst Gross expresses the opinion that there can be no doubt "of the utility of this procedure in the class of cases under consideration." It is unnecessary to multiply the evidence for and against this operation. We coincide with Dr. Murdoch that the operation is a proper and useful one, and our personal experience bears us out in this statement.

The great disadvantage of the operation is in the tendency to retraction of the heel, a misfortune which many of us have witnessed, and it is the object of this short note to call attention to what we consider to be the mechanism of this retraction. Dr. Murdoch, in common with many others, lays the blame upon the unantagonized tendo-Achillis; and it is possible and probable that this is a factor in the production of the retraction, but if we consider the anatomy of the foot, with all its arches, we see that it is impossible for the face of the stump not to point downward when the weight of the body is thrown upon it.

The bones of the tarsus form an antero-posterior arch, with three points of support, the os calcis posteriorly, and first and fifth metatarsals anteriorly. The calcis does not occupy a horizontal position, but is directed upward and forward. The astragalus forms the keystone of the arch. The arches of the foot are maintained by ligaments and tendons. If now the anterior portion of the foot is removed, the calcis must yield when the weight of the body is brought to bear upon it, whether the tendo-Achillis is retracted or not. It is impossible for it to keep its normal position under these circumstances, and the head of the astragalus, and the anterior portion of the calcis are brought into contact with the ground. It has seemed to us that pressure upon the cicatrix would be best avoided by making a rather long and thick plantar flap, and a directly transverse dorsal incision above the line of the medio-tarsal articulation, so that when the astragalus and calcis are forced downward, the cicatrix might be above the line of pressure.

There is an advantage in securing the anterior tendons in the cicatrix, but whilst this gives a certain amount of flexion, it cannot prevent the sagging of the stump. If there is any indication that the tendo-Achillis is acting with undue force, it should undoubtedly be divided, or even resected, but we are convinced that the fault does not lie in

this condition nearly as much as in the one stated. It should always be our aim, however, to amputate in front of this joint when possible, as a better stump is secured if only a portion of the scaphoid and cuboid bones is retained.

LAPAROELYTROTOMY.

Dr. Alexander S. Clarke, of Brooklyn, in a recently issued Nancy thesis, dedicated to Gaillard Thomas, earnestly advocates the operation with which the name of the latter is so identified that it might with justice be called by it, if personal nomenclature were not so objectionable.

In discussing the reasons for the operation not having met with general acceptance, he denies that the one given by Skene is correct, to wit, because the operation resembles very much more in its method a surgical than an obstetrical procedure, but claims that the true one is the painful effect which the memory of the first laparoelytrotomies by Ritgen and Baudelocque have left. This reason, however, does not seem to us valid, for surely the failures of these operators could have but little influence in contrast with the remarkable successes recorded by Thomas, and especially by Skene, nor would it weigh with great European operators, like Leopold and Sänger, for example, if they really thought it the best method of artificial delivery in pelvic contractions.

Dr. Clarke publishes a recent letter from Dr. Thomas, in which he states that he regards "this operation as much superior in all respects to the Cæsarean or the Porro operation." So far as the last operation is concerned the statement may be at once admitted, for "the Porro" has recently so greatly declined in professional favor that its final abandonment seems near and probable. But with the successes which the Sänger method of performing the Cæsarean operation has recorded, the other part of Dr. Thomas's statement will not be generally admitted as correct. Clarke, in comparing the two methods—that is, "the Thomas" and "the Sänger" —claims that the former has been done in only five cases under favorable circumstances, and then all the women were saved, a result superior to that obtained by the latter. But, of course, neither he nor other friends of laparoelytrotomy can regard so small a number of cases, and thus selected, as establishing the relative value of this method.

One of his arguments in favor of laparoelytrotomy is that it avoids the "inevitable dangers of placental hemorrhage and peritonitis," belonging to the Cæsarean operation even when performed by the Sänger method. The means for avoiding hemorrhage in the latter operation are well known, and probably most operators will prefer a carefully made and accurate incision, the wound completely closed so that prompt union results, to a lacerated wound of equal size, even if no important organs or tissues are injured, and such accidents have happened to the best operators—a wound which cannot be at once closed, and which requires several days for its healing.

We observe that the author fails, as most others who have written upon the subject have also done, to give the case of Gianflome, in Italy, the operation having been done in 1857, the child saved, but the mother lost.

The Library of the Surgeon-General's Office is now being moved into the fire-proof building erected for its special use, on the southeast corner of the Smithsonian grounds, a full description of which appeared in The Medical News of September 18, 1886. During the removal the books, of course, are not available for reference, but it is anticipated that they will be rearranged by the beginning of September, and will then be again accessible for use.

The College of Physicians and Surgeons of New York announces that at the session of 1888–9, and thereafter, it will require preliminary examination of matriculants who do not hold diplomas or certificates from recognized colleges or schools of science. The examinations will be in writing, and will include English, Latin, arithmetic, algebra, and plane geometry.

Dr. Victor C. Vaughan reports that he has found tyrotoxicon in the ice cream which poisoned 150 people at Amboy, Ohio, on July 4th. A few drops of the poison extracted from the ice cream killed a kitten in ten minutes. He has also found tyrotoxicon in ice cream which poisoned 50 persons at Geneva, N. Y.

It is stated that the advertising or sale of patent medicines (secret or proprietary preparations) has been absolutely prohibited in Berlin, and sixty-one of them have been publicly denounced on account of disclosures made by chemical analysis.

REVIEWS.

The Healing of Arteries after Ligature in Man and Animals. By J. Collins Warren, M.D., Assistant Professor of Surgery, Harvard University, Surgeon to the Mass. General Hospital, etc. 8vo. pp. 184, pl. xiv. New York: William Wood & Co., 1886.

Inherited reputation is worth little, especially in this country, unless its happy possessor adorns it by addi-

tional achievements. Dr. Warren admirably fulfils this condition. His name is intimately associated with the famous medical department of Harvard College, and he has repeatedly shown that with his father's and grandfather's name he has inherited their ability for doing good work. The present book, in its matter, its beautiful mechanical work in printing, paper, and binding, and its fine plates, is the best work he has thus far done, and one that will add largely to his already enviable reputation. It is creditable to American surgery that such a work of laborious original research should be undertaken, and it will, we believe, long be the standard work in the English language on this all-important subject.

His first chapter, supplemented by a most extensive bibliography, covering no less than 235 titles, is an historical review of the subject and is an excellent foundation. Next he gives experiments on animals, then observations derived from man. Then follows an interesting and valuable investigation of the closure of the fœtal vessels, a happy study of a normal obliteration of the calibre of these vessels. The book closes with a short but clear and admirably written summary of his investigations.

He has done the subject an important service in drawing attention to the analogy between the processes of repair in ligated vessels and in broken bones, and he is to be felicitated on his naming the granulation tissue about the ends of the vessels at the seat of ligature the internal and external provisional callus, and in tracing the analogy between the osseous and the vascular changes that occur.

We have not space for a critical notice of the investigations he has made, but it is due to him to call attention to some few salient points. Thus, he has shown that the process of repair is not complete under from three to six months, and that the muscular cells of the middle coat are a prominent factor in the cicatrix. The analogy to bony repair is shown in the three stages which he enumerates as proved: (1) the immediate changes about the ligature; (2) the formation of the provisional callus; (3) the changes in the internal callus and the gradual absorption that follows.

A marked contrast is noted in the thrombi in septic and aseptic wounds, and it is such as to leave no doubt as to the influence of septic products upon the process of coagulation. He shows, also, that all the mechanical devices of different kinds of ligatures and of different modes of ligation are far less important than that immediate repair without suppuration be obtained, as is now possible with antiseptic surgery.

He denies the hitherto taught primary importance of proliferation of the cellular elements, and exalts the granulation tissue which forms the callus into the most important element. "The sole function of the ligature after it has closed the vessel is to keep the walls from expanding until they are held sufficiently firmly by the callus," and while the thrombus which, he states, is always to be found, is becoming adherent to the walls; the two forming an efficient barrier to secondary hemorrhage.

This book should be not only read but studied, and its teachings incorporated into the lectures on surgery of all our medical schools—a compliment we can but rarely extend to any author.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Twentieth Annual Meeting, held July 10, 1887, at New London, Conn.

(Specially reported for THE MEDICAL NEWS.)

(Concluded from page 132)

AFTERNOON SESSION.

DR. CHARLES H. BURNETT, of Philadelphia, presented the report of

AN EXAMINATION OF FIFTEEN DEAF MUTES BY MEANS OF MALONEY'S OTOPHONE.

The cases examined were pupils in the Pennsylvania Institution for the Deaf and Dumb, Philadelphia, and were between the ages of twelve and twenty-one years of age. The cases were divided into three classes: 1, congenital cases; 2, those losing their hearing between the ages of one and five years; 3, cases of profound hardness of hearing but who can still hear a little and can talk, so-called semi-mutes.

The method of procedure was as follows: five vowels were written and pointed out at the time of their repetition three times in succession through the otophone by Mr. Maloney. The pupil was then told to indicate which vowel was spoken when Mr. Maloney made another repetition, care being taken to mix about in the tests. The words Philadelphia, Mississippi, Burlington, Missouri, boy, baby, papa, and mamma were also used as tests as well as the consonants.

Hearing was excited in every instance; but fourteen of the fifteen cases gave ample evidence of hearing by their successful indication with the pointer as the different tests were repeated in their ears. It was noted that the results were not so good with the acquired cases as in the so-called congenital cases of deafness. This may be due to the fact that the process productive of the acquired form is more violent, involving the internal ear more often than in congenital cases, which generally give evidence of being simply catarrhal in their origin and affect the middle ear but not the internal auditory organ. In the case of semi-mutes the results were especially satisfactory, as they heard nearly everything said to them and returned intelligent answers to the questions. In such cases both the remaining hearing and the articulation could in all probability be improved by the systematic employment of such an instrument as the otophone as a means of instruction, the best results being obtainable where the instruction is begun in early life.

A paper with the same title was forwarded by Dr. F. B. Loring, of Washington, and was read by title.

DR. WM. W. SEELY, of Cincinnati, asked whether the use of this instrument was recommended simply as a help to hearing or as a therapeutic measure?

DR. C. H. BURNETT replied that the instrument seems to be an immediate help, and is also a valuable therapeutic measure. In the case of an extremely deaf person who was unable to hear a loud voice when the words were spoken close to the ear, and who with an ordinary ear trumpet could hear slightly, with this instrument he could hear fairly well from the

first. After exercising for fifteen minutes, he was able to hear with closed eyes the unaided voice, the words being spoken a foot from the ear.

Dr. Sexton, of New York, presented a paper on

EXCISION OF THE OSSICLES OF THE DRUM OF THE EAR FOR CHRONIC PURULENT INFLAMMATION OF THE MIDDLE EAR TRACT.

Since bringing this subject to the attention of the Society, one year ago, he has continued the practice with satisfactory results, and presented some further observations based upon the records of nineteen operations. Of these nineteen cases thirteen were females and six were males, seven cases were between 5 and 12 years of age, eight were between 13 and 20 years of age, and four were between 23 and 40 years of age. The left ear was affected in eleven cases, the right in eight. In two cases both ears were the seat of suppurative inflammation, and in one there had been a mastoid abscess. In the majority of cases there had been a history of recurrent aural catarrh for a long time attended with pain in the ear. There were much deafness and distressing acoustic phenomena as autophonia and the like. The discharge was usually offensive. The general health of most of the patients was fair.

In all cases the drum-head was greatly impaired, the membrana vibrans being usually almost entirely gone; in most of the cases the membrana flaccida alone remained, perhaps with some portion of the membrana vibrans attached. Where any of the latter remained, it was liable to be found connected by bands with the inner wall of the tympanum. Sometimes a sinus of greater or less size opened through these diseased structures into the attic. The membrana flaccida, together with the membranous and ligamentous attachment of the ossicles, generally held the latter in place after the most extensive suppuration had long existed. Under these circumstances drainage was extremely likely to be interfered with. The manubrium and cicatricial structures depending from the auditory plate were frequently found adherent to the inner wall of the tympanum, while the attic and antrum were lined with much thickened mucous membrane.

Some portion of the middle ear tract was found to present more or less carious bony surface. In some instances the ossicles themselves were carious or ankylosed. In several of the cases the malleus handle was adherent to the inner wall of the drum. In some only a necrosed stump remained. In some the malleus and incus were adherent to each other. The incus was less liable to caries. The stapes cannot be so well examined as the other bones, since it is never removed. In some of the cases the operation was not resorted to until months or years after the ordinary methods of treatment had been resorted to without success.

Without going into all the details of the operation, the author said that experience had shown that it may be performed much more rapidly than was at first supposed. The first operations required an hour, the later ones not more than fifteen minutes. To the protracted operation he attributes some disagreeable symptoms, such as nausea, which had not been presented by the later cases.

The remaining fragments of the drum-head are everywhere detached from the tympanic ring with a slender trowel-shaped knife. The malleus is then freed from its attachments, including the tensor tympani muscle, by one or more sweeps of the knife. After all blood is removed, the long process of the incus is separated from the stapes if it be connected with that bone. The malleus handle is separated from the inner wall of the canal if it has been attached. The malleus handle is seized with stout forceps as high as possible and gradually detached and brought away. The removal of the incus is more difficult, since its long process is liable to be swept from view; with a little patience, however, the bone may be soon found, and its removal is then a simple matter. When lying in the attic the scraper may be of service in bringing it down. In most instances he no longer divides the chorda tympani. In some cases where the ossicles were very adherent, considerable force was necessary to detach them, and in one instance this was impossible.

After the operation the drum should be carefully dried with cotton and ten drops of a four per cent. solution of cocaine may be instilled. This is usually unnecessary. Usually very little or no reaction follows the operation. In females it is important to defer operation until a little time after the menstrual period.

In the nineteen cases both malleus and incus were removed in ten. In one the body of the incus alone was removed. In six cases the malleus only was excised.

When possible it is well to clear the drum of granulation tissue by treatment before the operation, since less hemorrhage will then be encountered. The duration of treatment after the operation was in 5 cases, one month; in 2, two months; in 2, three months; in 1, six months; and of the other 9 cases, 3 were unimproved, 1 failed to continue treatment, and 5 are yet under observation. Nine cases progressed steadily to a complete cure; 6 were much improved; 3 were unimproved, and 1 failed to continue treatment. Many of these were dispensary patients under bad physical conditions. A marked improvement in hearing occurred in nearly all cases. In the cases noted as cured, it was increased from 75 per cent. to 100 per cent., so far as testing with the voice was concerned.

This marked improvement in hearing was unexpected, and gave rise to the conjecture that we may recommend the operation for deafness alone in many cases where the drum is obstructed by the results of chronic purulent inflammation, although all discharge may have ceased.

It might be expected that the taste would be affected by injury to the chorda tympani nerve. In a few this was the case for a short time; recovery, however, always took place. Reproduction of the drum-head never took place. Among the results of the operation, may be mentioned the prevention of recurrent accumulations of purulent matter in the attic and antrum. The general health was nearly always improved. In two phthisical cases the cough was lessened in one and ceased in the other, whilst both gained much in weight. In children the effect on health was most marked.

The operation is performed with the patient upon the back and under ether narcosis. The electric light is almost essential. Magnifying lenses introduced into the speculum are of service. The after-treatment consists in keeping down granulation tissue and in aiding

in the transformation of the mucous lining into a dermoid condition. A meddlesome plan of treatment is undesirable. Where a large secreting tract exists a cure is sometimes almost impracticable. Alcohol has not been found useful in treating granulation tissue. Salicylic acid and boric acid have done good in a few cases. The peroxide of hydrogen has its use in certain cases. The persistence of discharge after operation may be expected in catarrhal and run-down subjects, especially where caries of the bone exists.

The specimens removed in these nineteen cases were presented.

Dr. Burnett stated that he had seen seven cases that had been operated on by Dr. Sexton. One case was of fifteen months' standing. There was no evidence of reproduction of the membrane. In the longer cases there was no discharge. In the cases more recently operated on there was still some discharge. In five of the seven cases, according to the statements of the patients, the hearing had been greatly improved.

Evening Session.

Dr. Theobald reported a case of

SYPHILITIC DISEASE OF THE LABYRINTH

exhibiting remarkable variations in the degree of deafness.

The patient was a man of about thirty-four years of age, the subject of inherited syphilis. In one ear the deafness was nearly complete, and in this ear there was little variation. In the other ear, frequent and sudden relapses occurred, after the hearing on several occasions had been brought up almost to the normal standard. Within twenty-four hours the hearing would fall from the ability to distinguish words in a whisper at twenty inches to a degree of deafness which would require the same words to be spoken in a loud voice. Iodide of potassium was given with but little effect, but decided benefit resulted from the administration of bichloride of mercury in combination with muriate of ammonia.

Executive Session.

The following were elected

NEW MEMBERS,

Drs. J. C. Lundy, of Detroit; Wm. H. Hotchkiss, of New Haven; S. D. Risley, of Philadelphia; and David De Beck, of Cincinnati.

OFFICERS FOR ENSUING YEAR.

President.—Dr. J. S. Prout, of Brooklyn.

Vice-President.—Dr. George C. Harlan, of Philadelphia.

Secretary and Treasurer.—Dr. J. J. B. Vermyne, of New Bedford, Mass.

Representative on Executive Committee of Congress of American Physicians and Surgeons.—Dr. C. R. Agnew, of New York.

Alternate.—Dr. Wm. H. Carmalt, of New Haven.

The next meeting of the Society will be held at the Pequot House, New London, Conn., Tuesday, July 10, 1888.

Adjourned.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-third Annual Meeting, held at New London, Conn., July 20 and 21, 1887.

(Specially reported for The Medical News.)

(Continued from page 156)

THURSDAY, JULY 21ST.—SECOND DAY.

GLIOMA AND PSEUDO-GLIOMA.

Dr. H. D. Noyes, of New York, wished to record the case of a girl who, when fifteen months old, had an eye enucleated for glioma of the retina, and who was living in good health, at the age of sixteen years. There had been no recurrence, and an artificial eye was worn constantly with comfort. The enucleated eye had been examined microscopically by Dr. Delafield and pronounced gliomatous. Another case had been seen eight years after enucleation of an eye for glioma, still in perfect health.

A boy aged five years fell, wounding his face and the lower edge of the orbit. Ten days later his mother noticed he could not see with that eye. After six months, light-perception had been lost; scleral vessels injected, iris slightly greenish, tension diminished, vitreous chamber partly occupied by a grayish highly vascular growth. Dr. H. Knapp joined in a diagnosis of pseudo-glioma. The eye was enucleated. Sections of it were exhibited showing an inflammatory mass and detached retina. The trouble seemed to have been caused by injury to the floor of the orbit, adjoining which the orbital fascia was hypertrophied and cicatricial. Before the enucleation no evidence of orbital injury was detected.

Dr. S. Theobald had seen a boy who had an eye enucleated for glioma, living nine years later with no sign of recurrence. In this case there had been no microscopical examination, but the macroscopic appearances satisfied him that it was glioma.

Dr. H. Knapp thought it doubtful if permanent cure is possible in these cases; he had recently heard of the death of a patient ten or twelve years after such an enucleation. Another case, seen last summer, remained well, six years after the enucleation.

Dr. W. H. Carmalt, of New Haven, agreed with the last speaker as to the tendency of the sarcomata to recur ultimately, and become general even after complete removal. He remembered the case of a babe six months old, blind in both eyes, where the diagnosis of glioma was made by several experts; and the eyes enucleated. But the microscopical examination revealed only a congenital detachment of both retinas.

Dr. J. S. Prout, of Brooklyn, had seen a case of pseudo-glioma go on to rupture of the eyeball posteriorly and kill the child. Here was additional reason for the removal of such eyes.

Dr. B. A. Randall had seen a case in which Dr. McClure had enucleated for glioma seventeen years before. He did not know of any microscopical diagnosis of the case. The patient was still well, and there had been no asymmetry in the development of the orbit.

Dr. E. Gruening had seen a girl aged five years operated on in 1875 for true glioma; and a girl aged one year operated on in 1879 for the same trouble.

There had been no involvement of the optic nerve in either case. Both were still healthy.

Dr. B. E. Fryer, of Kansas City, had, in two cases of intraocular tumor with hazy vitreous, had great assistance in making the diagnosis, from the electric light.

Dr. Noyes said he was sometimes able to make a positive diagnosis of glioma, in other cases he could not give an opinion without a microscopic examination. He used highly condensed light from a four-inch condensing mirror, and examined doubtful surfaces under a strong magnifier.

Dr. Knapp had used condensed sunlight.

Dr. W. S. Dennett, of New York, had used all kinds of light. The main thing was to get enough of it. He thought the electric light the most constantly available and most manageable.

Dr. H. D. Noyes reported a case of

removal of a prolapsed lachrymal gland.

A girl aged twenty came with the history of a swelling under the upper lid that had been growing for nine years. It was brought to view by raising the lid, and extended within six mm. of the cornea. It was quite movable, very elastic, and free from pain. A much smaller mass presented in a similar position on raising the lid of the other eye. The larger mass was removed, and proved to be the normal lachrymal gland, which seemed to have taken this abnormal position simply by reason of an undue laxity of its fibrous capsule. No unpleasant effects followed the removal.

a suggestion for the relief of entropion of the lower lid.

Dr. H. D. Noyes had operated four years ago for entropion of the lower lid by dissecting up a narrow strip of skin from below the base of the lid, and after removing a little conjunctiva from the lid toward the outer canthus, had attached the end of the strip at this point. Last winter the patient returned with the lid in good position, but with the little bridge, or bridle, of skin still fast to it. This little band was removed, leaving a perfect cure of the entropion.

Dr. John Green, of St. Louis, had formerly practised the operation of making an incision through the skin near the base of the lid, and parallel to the lid border. The skin of the lid was then dissected up, and drawn down and attached lower on the cheek. This gave a good immediate result, but it was not permanent. Latterly he treated entropion of the lower as he did that of the upper lid, adding to his former operation an incision parallel to the lid margin, upon its inner surface. This had rendered the operation more effective, and its good results more permanent.

Dr. W. W. Seely, of Cincinnati, asked if this was not simply the Hotz operation practised on the lower lid.

Dr. Green said that it differs from the operation, known in this country by the name of Dr. Hotz, in not splitting the lid. The second incision is fairly on the inner surface some distance back from the orifices of the Meibonian glands; and it sacrifices no skin. It was the operation commonly practised by the ancients on the upper lid; but they, on the lower lid, merely removed a large piece of skin.

Dr. E. Gruening had used the Hotz method, putting the sutures through the whole thickness of the conjunctival sac except the skin. He removed nothing, and had found entropion of the lower lid as easy to remedy as entropion of the upper lid.

Dr. Noyes believed that there were cases where this expedient of a "buckle" of skin to hold the lid in position would be found useful.

a phenomenal pulsation in the interior of the eye.

Dr. W. F. Mittendorf, of New York, had observed this in the eye of a patient with hyperopic astigmatism and asthenopia. The fundus and the tension of the eye were normal. There was no spontaneous pulsation of the vessels. On the disk the perivascular sheaths were particularly well marked. Above the disk there was, stretched between two vessels, a bag or band of gray which pulsated synchronously with the action of the heart, although not the slightest movement could be seen in the vessels. Higher, and to the nasal side, there was a gray shred attached to an artery that pulsated when sufficient pressure was made on the globe to cause ordinary arterial pulsation. The conclusion of Dr. E. G. Loring and himself was, that the former appearance was a connective-tissue band, and not a bag connecting two perivascular sheaths.

Dr. L. Howe wished to call attention to the pulsation tracings which could be obtained from the normal eye, by a form of plethysmograph adapted to it.

Dr. E. Jackson had seen a tag of connective tissue attached to a perivascular sheath, hanging out over a rather deep physiological cup on the disk, which pulsated when no pulsation was apparent in the vessels. Both eyes presented this phenomenon.

increase of blindness in the united states.

Dr. L. Howe, of Buffalo, called attention to the fact, that while the population during the ten years from 1870 to 1880, increased 30 per cent., blindness during the same time increased over 140 per cent. By means of a diagram, the percentage of increase in each State separately was shown. The statistics also show that blindness increased in an almost constant ratio from north to south, and that it decreased in the same way from east to west. This was also shown by colored maps. The cost of sustaining this army of over fifty thousand blind was estimated, on the lowest basis of cost and of wages which would have been earned, at over sixteen million dollars in 1880, or twenty-five million dollars in 1887. As for the causes, contagion was found to exercise the most important influence. This was found by a special examination made for the pupose of 128 pupils at the Batavia Asylum for the Blind; by the statistics collected by Magnus, and by the records of over forty-eight thousand cases treated at the Manhattan Eye and Ear Hospital. Immigration was also considered as an important factor in view of the large number of cases of contagious diseases of the eyes introduced every year into the country, and the laxity or absence of quarantine regulations regarding them.

Dr. H. D. Noyes noticed that the increase of blindness was especially marked in States with great mineral resources, where large numbers of the population would be liable to mine and mill accidents, etc., and where it would be difficult or impossible to obtain skilled atten-

dance for such injuries. Some means should be devised for the relief of such cases.

Dr. G. C. Harlan, of Philadelphia, called attention to the uniformity in the proportion of blindness due to conjunctival disease, as shown by different sets of statistics.

Dr. S. M. Burnett thought that in connection with locality the influence of race should be considered. Negroes form a large proportion of the population of the Southern States, and they are almost entirely exempt from trachoma, although especially liable to scrofulous affections of the cornea.

Dr. W. F. Mittendorf was not surprised at the increase of blindness; he thought it due largely to the crowding of young persons into public institutions.

Dr. P. A. Callan, of New York, asked: What can be done to check it? Should not societies be organized in every large city to instruct the public in the care of the eyes?

Dr. M. Standish, of Boston, in a dispensary service where a large proportion of the patients were Irish, and where there were many cases of trachoma, had noticed that most of the flagrant cases of this affection appeared among those who had lately arrived in this country, as though it had been contracted during the passage in the crowded steerage of the emigrant ships.

Dr. Howe offered the following, which was adopted:

Whereas, The Census reports indicate there has been an increase in the number of blind in the United States more than four times as great as that of the total population; and

Whereas, An inquiry as to the causes of this shows that it is largely due to contagious diseases of the eye, therefore

Resolved, That a committee of three be appointed to examine further as to this apparent increase, and recommend means for its prevention.

Resolved, That the President of the United States and the Secretary of State be respectfully requested to furnish this committee with whatever letters or other recommendations may be necessary to further their investigation in this country or elsewhere.

Resolved, That officials in charge of residential schools and similar institutions be also requested to assist the committee to any extent in their power.

Dr. L. Howe, of Buffalo, was appointed chairman of the committee, and the President was permitted to announce the other members at his leisure.

THE EYE OF THE ADULT IMBECILE.

Dr. C. A. Oliver, of Philadelphia, had examined twenty young adult male imbeciles. Nineteen observations were obtained, with the following conclusions:

First. The eye of the male adult imbecile is an organ which is capable of proper functional activity.

Second. By reason of early mental incapacity, the ordinary appearances seen in the used eyes of the mentally healthy are lessened in due proportion to the amount of work given to the organ.

Third. The eye of the imbecile being practically an unused organ for close and careful near work, the distention of the globe and elongation of its visual axis with consequent increase in refraction, is almost entirely avoided, this being in direct ratio to use.

Fourth. The want of these physical changes may be considered as significant of a type of the unused healthy human eye.

Fifth. The healthy eye of the imbecile serves to teach us that the various conditions seen in the used eye of the mentally healthy must be considered as pathological changes, the representatives not only of general want of tone, but of constant and frequent abuse of a delicate organ.

Dr. E. Jackson said that the author had spoken of being unable to test the accommodation of imbeciles. In the shadow-test with the plane mirror, we have a reliable and convenient method of measuring the accommodation.

CASES ILLUSTRATING CHANGES OF FORM IN THE EYEBALLS.

Dr. S. D. Risley, of Philadelphia, reported nine additional cases of eyes with hypermetropic refraction passing, while under observation, into myopic refraction, through the turnstile of astigmatism; the first and last states of refraction being determined with complete paralysis of the accommodation. The importance of the existing astigmatism was insisted upon as a cause of the eyeball distention; and, therefore, the careful correction of the astigmatism was regarded as of great importance in the treatment of these cases.

All of these cases yet presented to the Society—twenty-two in number—were characterized by asthenopia, aggravated by use of the eyes, retino-choroidal disturbance, diminished resistance to normal intraocular tension, and slow distention of the sclera. They were all partially or completely relieved for a time by the correcting glasses, and other treatment employed, and in some of them the trouble returned only when the glasses were neglected. He believed that in a much larger group of cases this process was going on, and would have continued to progress if it had not been checked permanently by the use of the correcting glasses. One of the cases, that of a lady about fifty, illustrated the fact that these changes were not confined to youth.

Dr. W. W. Seely thought that lack of the proper balance between opposing extraocular muscles, is a most frequent factor in such changes of refraction.

Dr. Risley had for many years made it a routine practice to test that balance; in only three of the cases reported was it incorrect. These exhibited insufficiency of the interni. Two were relieved by tenotomy of the externi, and the third by prisms. He felt confident that astigmatism was the important factor.

Dr. H. Knapp asked the opinion of the members as to the power of correcting astigmatism by voluntary unequal contraction of different parts of the ciliary muscle.

Dr. Seely had a patient who could correct 1.5 D of astigmatism after leaving off his glasses for a little time, but the power of doing so was not strictly under control of the will.

Dr. S. M. Burnett thought that, undoubtedly, there were such cases, and that a practical point was that the astigmatism might be different for near, from what it was for distant vision.

Dr. B. A. Randall had seen several cases of marked increase in the degree of astigmatism under the use of a mydriatic. In one case this amounted to 3 D.

Dr. W. F. Norris said that almost every case of hyperopic astigmatism can make the horizontal, then the vertical lines alternately clearer, especially if there be any retinal irritation.

Dr. W. H. Carmalt thought that cases in which astigmatism was corrected or aggravated by contraction of the ciliary muscle were so common, that the point should be regarded as settled.

Dr. Theobald was able to vary, within certain limits, the strength of the cylinder correcting his own compound myopic astigmatism, without impairing his acuteness of vision.

Dr. Risley thought that only in mydriatic paralysis did we get the true refraction of young persons. But he had never satisfied himself of the existence of power to change the astigmatism by voluntary unequal contraction of the ciliary muscle. Astigmatism might be partly corrected by changing the shape of the cornea through pressure, particularly by the lids.

Dr. Knapp thought astigmatism could be partly corrected by pressure from without, but not of the lids. In most cases, the principal meridians were such that pressure of the lids would aggravate the astigmatism.

THE PATHOGENESIS OF PTERYGIUM.

Dr. S. Theobald, of Baltimore, urged that any theory that attempts to explain the causation of pterygium, must account for the fact that it always occurs over the insertion of one of the recti muscles into the sclera, and usually over the insertion of the internal rectus. Existing theories do not do this. The one ascribing pterygium to injury and ulceration of the cornea, at the margin of the conjunctiva, ignores the fact that the process often starts in the conjunctiva, some distance back from the cornea; while those ascribing it to conjunctival irritation fail to account for its especial frequency on the nasal side of the cornea. If, however, we suppose that pterygium be due, at least in part, to an influence which use of the recti muscles exerts on the blood supply of the conjunctiva over their attachments, these points are readily explained. Persons presenting this affection, often give a history of recurrent hyperæmia of the part after using the eyes. Then the internal recti are in closer relation with the conjunctiva covering their insertions than any of the other muscles; and are most frequently and severely taxed. The cases reported by Dr. J. A. Lippincott at this meeting, bear out this view.

Dr. D. B. St. J. Roosa said that in a large proportion of cases of pterygium, a history is given of traumatism as the commencement of the process. He thought persistent hyperæmia over the attachment of the internal recti quite common, but that it would not lead to such extensive proliferation of tissue.

Dr. Theobald held that some cases are doubtless due to traumatism, but these were only occasional, and often not situated in the usual location. But ninety per cent. of pterygia are situated at the nasal side of the cornea, and this, traumatism, or corneal ulcers will not explain.

Dr. J. A. Lippincott thought that persistent hyperæmia commonly produces hyperplasia of the part. Dr. Roosa's objection to the theory seemed not well founded.

RECURRENT RETINAL HEMORRHAGES, WITH DEVELOPMENT OF BLOODVESSELS IN THE VITREOUS.

Dr. S. Theobald had previously seen the patient for refractive troubles. In April, 1886, there had been conjunctival injection, pain, and dimness of vision. The ophthalmoscope showed small hemorrhages above the disk. These increased in number for a few days, and the diagnosis of thrombosis of the upper retinal vein was made. In July, vision $\frac{20}{XL}$; in August $\frac{20}{XX}$. September 20th she had a fresh hemorrhage. In October there was a dark mass like a globule of blood below the disk. In January, 1887, there were fresh hemorrhages. February 22d, vision again $\frac{20}{XX}$. March 26th, a floating opacity was discovered in front of the disk, which was found to consist of small bloodvessels held together by semi-opaque connective tissue. By June 3d this had become smaller, and vision = most of $\frac{20}{XX}$.

Dr. W. H. Carmalt said that in February, 1877, a man consulted him for sudden blindness of the left eye, the vitreous being filled with blood. A month later there remained traces of coagula in the vitreous. In August the vision of the right eye was lost in the same way, and hemorrhage was found in the vitreous, with choroidal changes. In January, 1878, the left eye was again affected. When the hemorage cleared up, there were floating bodies in the vitreous, and a meshwork of bloodvessels extending far forward from the fundus. The nerve was pale, the veins rather large, and arteries small, and to the nasal side an artery ruptured, and an ecchymosis adjoining. The general condition of this eye and the new vessels in the vitreous continue the same. Every few months he has a fresh attack of hemorrhage, but lately these attacks have been confined to the other eye. The vessels seem to come from a point outside the nerve.

Dr. B. E. Fryer had seen one case of recurrent retinal hemorrhage which he thought was due to scurvy.

Dr. O. F. Wadsworth had seen, ten years ago, in a man then over thirty, extensive hemorrhage into the vitreous of one eye, which was clearing up, when hemorrhage occurred into the retina of the other eye. The fundus of this second eye seemed otherwise normal, except spots of perivasculitis near the equator, and on one vessel a fusiform white enlargement. Again, the first eye became almost blind from hemorrhage. After this, when the vitreous cleared, the retina could be made out, but with transparent membranes in front of it, carrying vessels in the vitreous, some of which could be traced to their connections with the retinal vessels. Two years ago there had been no recurrence of hemorrhage for over a year. The other eye early returned to the normal condition.

In another man, aged twenty-three, there had been sudden blindness from great hemorrhage into the vitreous. This afterward cleared up in a large measure, and he had a recurrence, after no special exertion, just as he was getting into bed. The sight was afterward lost.

Dr. H. Knapp had treated these cases as he did lesions of the choroid. But the main point was to avoid

fatigued the eyes, and to put them to rest early in the evening. A waitress, well treated by the family with whom she lived, almost always had such hemorrhages when the family had given an evening party, and when she would be kept up late and much fatigued.

EMBOLISM OF THE CENTRAL RETINAL ARTERY.

DR. G. C. HARLAN, of Philadelphia, reported the following case: The patient was a clerk, fifty-two years of age, in good general health. While reading with perfect comfort, a shadow suddenly appeared before his left eye; and, on closing the other and looking up, he could just distinguish large objects about the room, through a "brownish mist," and in a few minutes sight was entirely gone. An ophthalmoscopic examination, made the next morning, showed an extensive œdema of the retina, giving the whole fundus a grayish tinge; disk pale, and its margins blurred; arteries very pale, though not much narrowed, and some of the smaller branches lost in the retinal œdema; large veins contracted in places, particularly on and near the disk, but generally of full calibre; phenomenon of visible, slow, continuous circulation of the blood in bead-like sections, well marked in superior temporal artery and vein; macula occupied by bright red patch, oval in form, with long diameter horizontal, and several of the minute terminal vessels in the neighborhood unchanged, and apparently isolated; two small dots of retinal hemorrhage at outer margin of the disk.

The œdema increased decidedly for the first few days, and then gradually subsided. There was still a little remaining on the nineteenth day, after which the patient was not seen for three weeks, when the color of the fundus was normal. The visible circulation lasted only about a day and a half, disappearing first in the artery. The veins refilled at their narrowed portions, and retained nearly their normal calibre, while the arteries became paler and narrower, until only the two main trunks could be seen, and these showed white lines along the margins from perivasculitis. The spot at the macula gradually disappeared. The disk regained the distinctness of its outlines, and remained dead white. (Colored plates were shown, illustrating the first and the final appearance of the fundus.) The pathology of the case was very obscure; the heart and kidneys were normal, and there was no symptom of degeneration of the arteries. A caries of the middle turbinated bone on the same side, from long standing nasal catarrh, was not thought more likely to act as a cause than would be a similar local disease in any other part of the body. The only possible causes seemed to be that some product of the nasal disease might have found its way into the general circulation, and lodged in the retinal artery; that an embolus might have been formed of a fragment washed from a parietal thrombus in some distant vessel; or that the obstruction might have resulted from disease in the retinal artery itself.

SIMPLE GLAUCOMA.

DR. D. COGGIN, of Salem, Mass., reported a case in which the left eye, after gradually failing for four years, had become entirely blind, with the characteristic excavation of the disk. The other eye, then, with correcting glass, had full vision. Subsequently its tension increased, and vision fell to ¼. The pupil remained normal, eserine had no influence in arresting the disease. Iridectomy was done, and there had been no further advance in the process in the eighteen months that had since elapsed. Does not the performance of iridectomy offer these cases more hope than any other measures? Other cases were reported, which, without operation, went on to complete blindness.

THE DANGER OF USING OLD HAMMERS.

DR. G. C. HARLAN had his attention called to this by a patient, whose eye had been penetrated by a scale from a hammer he was using. After long use the metal in a hammer becomes crystallized and very brittle, and a layer forms at the surface that is extremely liable to be chipped off. A hammer showing such a layer was exhibited.

(To be concluded.)

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, held at Long Branch, N. J, July 21, 22, and 23, 1887.

(Specially reported for THE MEDICAL NEWS.)

(Continued from page 138.)

THURSDAY, JULY 21ST.—MORNING SESSION.

DR. J. H. LLOYD, of Philadelphia, presented a

NOTE ON A CASE OF INSANITY OF DOUBT.

These cases are characterized by a special form of delusion which differs radically from the delusions either of grandeur or persecution. They are changeable, negative, vulnerable, and confessed with timidity and mortification. They are somewhat allied to melancholic conditions, but are not characterized so much by depression of spirits as by confusion and perplexity of mind. The patient is apt to recognize the morbid character of the mental state, and will willingly take measures to counteract and cure it.

He related the case of a lady brought from a distant city to Philadelphia, to be placed in a hospital for the insane. During the preceding year she had shown change of character and habits, and had developed some well-marked symptoms of the *folie du doute*. She had been known to get in and out of bed at least twenty times on retiring at night, because of some morbid train of associated ideas which made her feel that she had not performed the act aright, and that unless it was done in a certain precise manner it would in some way be the cause of disaster to her, producing disease or her death before morning. So again, recently, she obliged her husband to remain in her room with her, after arising, until she had put on and taken off again, innumerable times, one of her skirts, apparently from a morbid impulse of the same kind. In order to be rid of those morbid promptings, she is impelled to resort to little tricks, repetitions, and foolish actions, which explain the erratic conduct of which she is guilty. Thus, when dressing, she obliges her husband to hold a pin for her, which she must seize at just the right moment, otherwise the toilet must be made again. She has sometimes insisted upon this long-suffering husband rising in the night, going down stairs, lighting a certain gasburner and extinguishing it again in just a certain way, because this was necessary to absolve her in some

manner from some of her morbid doubts and associations; and she has not been content until her husband has humored her.

She is a woman, about thirty years of age; rather under weight for her build; of not very good color and complexion; of sound muscular system, but not well developed, and suggesting rather physical than mental impairment, and that not serious. She said that she knew perfectly that her notions were morbid, and hoped to be able to conquer them with improvement of her health by horseback and outdoor exercise. But she opposed being placed in an asylum, and threatened, if she were, suicide. Her husband was advised to take her home, but, if with time the case grew worse, to place her in an asylum.

The several cases which he had seen, have all probably been of the neurotic or constitutional type.

Dr. Mills had seen this patient and concurred in Dr. Lloyd's opinion. Extreme care should be used in committing these cases to an asylum, for if they be brought into court but few juries would adjudge them insane, although he did not doubt their insanity.

Dr. Gray remarked that he had no doubt that these cases are insane, and should not hesitate to put them under restraint, but would not do so unless he well knew the antecedents. In his experience he had found them exceedingly dangerous, as a number of them will go a long time without manifesting dangerous symptoms, when some day they will commit some terrible deed. He cited a case in which a woman had been in an apathetic condition for some time, who had, by actual count, washed her hands four hundred times in one day, and yet for all medico-legal purposes would have been considered sane. She had become debilitated owing to neuralgia and some uterine difficulty, but her mind seemed to recover somewhat under careful medical treatment. He, however, decided to send her to Bloomingdale, and so informed her, stating the result he hoped to attain in her case; but the day before she was to go, she, unfortunately, quarrelled with her mother on some trivial matter and set fire to her own clothing, having secretly procured and hidden matches about her person. He deemed them especially dangerous when left with children.

Dr. Landon Carter Gray read a paper on

CHOREA,

which, he said, has been considered as a self-limited disease of an average of ten weeks' duration, but he considered it more serious than has been allowed. Of 134 cases noted in his records, 17 have had one relapse, 4 have had two, 3 have had three, 1 has had five. In 23 the disease was distinctly chronic. He then gave the statistics of the remainder, some suffering from hysteria, and some from convulsions, some also from a neurosis; two were fatal. The mortality in pregnant women he placed at twenty-five per cent. He considered it to be greatly increased by mental impression ending in chronicity or cure. One peculiar case was quoted in which red, painful spots appeared at the ankle as premonitory symptoms, the following day choreic symptoms were shown, and the painful spot had disappeared. After a careful retrospection of his case, the writer had come to the conclusion that rest in bed was the best remedial agent. Eight years ago he had concluded that arsenical treatment was the best method to be pursued, but he had since discovered his mistake, and that arsenic was but temporary in its effect. He also used large doses of dialyzed iron, thirty minims to two drachms well diluted; galvanization of the spinal cord also being of benefit.

Dr. Starr inquired as to the probability of adults becoming insane after developing chorea, as in some cases he had noticed a tendency to melancholia.

Dr. Lloyd remarked that he had noticed in a pregnant woman a tendency to mental impairment.

Dr. Dercum asked if he had had any experience with cimicifuga.

Dr. Hammond said that in his practice he used arsenic almost exclusively, and in anæmic cases combined it with rest and tonic treatment.

Dr. Edes mentioned cases which had passed into insanity, but had afterward recovered.

Dr. Gray considered choreic insanity of very rare occurrence; as to whether the choreic patient was more prone to insanity that he could not say. In regard to cimicifuga, he considered it as a tonic in this disease, but he had not had much experience with it.

Dr. M. A. Starr, of New York, made some remarks

ON PARAMYOCLONUS MULTIPLEX, WITH REPORT OF A CASE.

He drew attention to the method of staining advocated by Weigert, the specimens being soaked in the solution before they are cut, and he exhibited specimens thus prepared.

Afternoon Session.

Dr. Dercum, of Philadelphia, reported

TWO CASES OF HEMICHOREA ASSOCIATED WITH BRIGHT'S DISEASE.

He called attention to the fact that the movements first commenced in the arm, next the face, and finally involved the whole body. This condition remained for two weeks, the motion being so violent as to interfere with sleep. A carbuncle appeared on the neck, and death finally resulted. At the post-mortem the vessels were found to be thickened and somewhat pale. The second case was that of a carpenter, sixty years of age, who had suffered from vertigo for several years. Suddenly he lost the use of his right leg. This lasted for two weeks, but he was perfectly conscious. He afterward fell a few feet from a scaffold, but escaped without injury. Unfavorable symptoms followed; albumen was found in the urine, and he passed water twice during the night; casts also being found in the urine. He asked whether there was any association of hemichorea with Bright's disease. In neither of these cases was there any history of hemiplegia.

Dr. Edes thought that these symptoms were not alone confined to Bright's disease, but that the general system was involved; that there are cases of hemiplegia which come and go very rapidly. He thought in Dr. Dercum's cases there was some disturbance in the circulation, but not enough to be detected after death.

Dr. Mills was inclined to agree with Dr. Edes, and thought that the disease produces unilateral depression of the general system. He had seen not a few cases

in which hemiplegia was developed in Bright's disease. He considered this to spring from a condition purely local, developed in the cerebrum from the uræmic poison; and at the post-mortem, unless under the most careful examination of the brain, he would find nothing that he could call a gross lesion. In general terms, we had an interference of circulation. Why it should be on the right side in one, and on the left in another, he did not know, and he considered it purely accidental. He thought chorea might be produced in this way.

DR. DERCUM remarked that, although he had made careful microscopical examination, he had found nothing but general œdema, and in one case slight sclerosis of the vessels, but not more marked on one side than the other.

DR. E. C. SPITZKA, of New York, read a paper on

ACUTE OR GRAVE DELIRIUM.

He considered that this condition might arise from various causes, commencing with insomnia, inability to collect the thoughts, and a feeling of impending misfortune; some may feel hilarious, some have illusions of hearing or touch; others, again, are passive. Both the temperature and pulse increasing, the symptoms denote extreme exhaustion; later on, before death, but just previous to this, the patient may become sane. He held that this condition was due to disturbed circulation, produced by morbid changes in the brain and perverting its function.

DR. GRAY remarked that he had had only one fatal case of this kind. One case had now been living three years, and was in an asylum; another lived for six months. One case had a history of syphilis. The fatal cases that he had seen had been so violent that they had to be restrained.

DR. MILLS stated that in three cases of so-called hysterical insanity which had been under his observation, two died and one recovered. He believed that two of them were cases of grave delirium.

DR. HENRY HUN, of Albany, reported a case of

GLIOMATOUS HYPERTROPHY OF THE PONS,

which will appear in full in an early issue of THE MEDICAL NEWS.

DR. M. A. STARR read a paper on

PARAMYOCLONUS MULTIPLEX,

based on the case of a grocer who previously enjoyed good health, but had recently strained himself in lifting a box. The pain commenced below the right shoulder and was so severe that he immediately consulted a physician, and while in his office was seized with a convulsion and screamed with pain. This was followed by spasms of the muscles of the trunk, with ten or twelve attacks in twenty-four hours, groups of muscles of the extremities gradually becoming affected, and spasm of the diaphragm was also observed. These spasms he could not control and any exposure to shock would produce them; they were more liable to occur under mental excitement, and pressure on the right shoulder at the seat of pain would produce them. The spasms of the muscles were very violent, but did not move the joints. Tapping of the skin would produce a spasm. He considered this affection a functional neurosis. This, he believed, was the tenth reported case. The disease was a spasmodic affection of the muscular system occurring bilaterally, and coming on in a series of violent clonic spasms occurring at intervals after violent physical or mental strain. Galvanism, arsenic, chloral, etc., had been found beneficial in the treatment.

DR. SPITZKA mentioned a case, but the patient was not quite equally affected on both sides of the body; the movements were 145 to the minute.

DR. DANA mentioned a case he had seen in which the movements of the muscles commenced at 5 and increased to 60 in the minute, but it did not resemble Dr. Starr's description in all points.

DR. MILLS could not see the necessity of dividing this from muscular tremor and making it a separate group, and thought it might be of interest for Dr. Starr to state the differential diagnosis. He had seen cases so closely resembling these that he thought they could all be classed under the same head.

DR. LLOYD had seen a number of cases of hysterical tremor which closely resembled the symptoms mentioned by Dr. Starr, and he was inclined to believe that there was hysteria in his case also.

DR. STARR stated that the affection was bilateral. He could not agree with Dr. Dana that it was a case of convulsive tremor. It was a question in his own mind whether the case was hysterical or not. He could find no trace of hysteria whatever in the case, although there might be; but he did not see why this should prevent these cases from being classified into certain groups.

(To be continued.)

CORRESPONDENCE.

LETTER FROM MUNICH.

The Hospital—Obstetrical Statistics—Prof. Winckel's Clinic.

The obstetrical and gynecological division of the hospital here has presented much of interest. The department is in a separate building, of modern construction, and as to light and ventilation, and in general appearance, seems to a cursory examination, entirely satisfactory. The University and Hospital are, like everything in Germany, under government supervision and regulation. There are over eleven hundred students, the medical course of study occupying five years—practically four and a half—and entrance to it must be from the gymnasium, the completion of the course there being guarantee of preparatory education. With the large number of students I have never seen together more than about fifty. It is not pleasant over here to hear the comments medical men make upon a system of education which permits a student to attend a gynecological or obstetrical clinic (if there be such) before he has finished his anatomy.

A few statistics from the official report of the obstetrical hospital may be of interest. The first may be novel: From May, 1884, to May, 1885, of 950 patients admitted, only 146 were married. In the following year, of 830 patients, only 68 were married.

From 1874 to 1883 there were 10,518 deliveries with 114 deaths; a mortality of 1.08 per cent. From 1883 to 1886, there were 2080 cases with 15 deaths; mortality

0.81 per cent. Of the deaths, 8 were from infectious and 7 from non-infectious diseases. The operations numbered 132—or 6.3 per cent. For a single year the operations were 61 in 941 cases, and presented the following:

Reposition of cord		6
Forceps:		
eclampsia,	1	
dilatation of cervix,	1	25
danger to mother,	2	
danger to child,	21	
Version (deformed pelvis, 3)		18
Perforation and cranioclasis		5

In the same year are reported 52 ruptures of perineum: of the first degree, 4; of the second, 45; of the third, 3. Also one laceration near the clitoris, giving rise to arterial bleeding. There were four cases of eclampsia, all recovered.

Of the 940 children, 106 died; subpartu, 60; fœtu macerat., 34; asphyxia, 4; rupture of uterus, 2; other causes, 6. Operations: forceps, 4; version, 5; perforation, 5—total 14.

Puerperal statistics: Of 950 cases, 707 were dismissed on the seventh day; after the seventh day, 213; sent to gynecological wards, 16; died within twenty-four hours of reception, 2. There were 242 cases of puerperal disease, among them: œdema of vulva, 44; puerperal ulcer, 107; partial gangrene of vulva, 2; cystitis, 3; parametritis lateralis, 29; bilateralis, 7; peritonitis, 4; pyæmia metastatica, 1; erysipelas, 3; phlebitis, ven. saph., 2; mastitis parenchymosis, 13; suppurative, 1.

The spray is not used during delivery, but every attention to disinfection by vaginal douches, and to cleanliness on the part of attendants is observed.

The departments of obstetrics and gynecology are under the care and direction of Prof. Winckel, and the lectures and courses of instruction are by him. The recent translation of his book on *Diseases of Women*, an honor it deserves notwithstanding the excellent works of our own countrymen, renders any introduction of him unnecessary. I witnessed his instruction in operative gynecology, of which two lessons of two hours each are given weekly. The soft parts are attached to, firmly sewed into, the phantom. Upon three such phantoms three parties of students performed the operations at once. One of the operations was total exirpation of the uterus per vaginam, and that it could be thus practised is sufficient evidence of the value of this method. It will be found described in *Archiv für Gynäkologie*, B. xxiii. H. 2. The soft parts are kept in a solution of corrosive sublimate and glycerine, and I was assured that careful record had been kept, and the observations showed that there had been no increase of puerperal diseases among women attended in labor by those students who were pursuing this course.

The operating hour is very early here—seven o'clock. I had the pleasure of seeing several operations by Prof. Winckel. The spray was used, but not thrown directly on the parts; a single apparatus threw its stream over and above patient and operator, and I was informed that outside of the hospital this would be dispensed with. The first case witnessed was extirpation of ovaries, or Battey's operation, for hemorrhage from a myoma. The patient was forty; the tumor somewhat larger than a cocoanut. The operator first scrubbed the abdomen with soap and brush, and disinfectant solution; then covered the abdomen, except the seat of operation, with soft towels wrung out of the solution. A colpeurynter was introduced into the vagina and distended with water, in order to raise the tumor out of the pelvis. Considerable difficulty was experienced, even after extension of the incision, in getting the tumor out of the abdomen, on account of its being very smooth and round. The colpeurynter was removed, and the tumor lifted up by the fingers of one hand in the vagina, and then turned out of the abdomen, great care being taken, of course, not to wound it. The ovarian pedicles were then tied with silk, and divided, the tumor afterward replaced in the abdomen, and the wound closed.

I also witnessed two ovariotomies, neither of which presented anything very extraordinary. The pedicle was transfixed and tied, no particular method or special "knot" being used, but it was efficiently done. Then, instead of cauterizing the part of the pedicle above the ligature, the peritoneum was drawn over it and stitched together with fine catgut. In one case the pedicle was quite short, and necessarily suffered some tension during ligation. Under such circumstances, Prof. Winckel emphasized the necessity of a careful inspection of the pedicle below the ligature for possible slight ruptures or lacerations which may give rise to consecutive hemorrhage. Such a tear was found in this case, and closed with fine catgut sutures.

After the laparotomies, the toilet of the peritoneum was very gentle and restricted. The abdominal wound was closed with silkworm gut sutures, introduced from without inward, and from within outward, the peritoneum and all the tissues of the wall included, and each one tied as soon as passed. The wound was then covered with pieces of iodoform gauze, aseptic cotton laid over the abdomen, and a wide roller bandage of loose material turned on.

I had the pleasure of seeing these three patients five or six days after the operations, with temperatures but little above normal, and doing well every way. No dressing of the wound is made until the seventh or ninth day.

I witnessed also an Emmett's operation. The "ectropion" was scarcely more marked than a number of cases seen in Italy, where the real nature of the lesion was not recognized. Prof. Winckel uses the scalpel altogether for paring, and closed the parts with silkworm-gut sutures introduced with an ordinary well curved surgical needle, just such as was used in closing the abdominal wound after laparotomy. These details are mentioned because great weight is laid by some upon the especial method of, or peculiar instrument for, certain operations, and this seems to be the case particularly in gynecology. R.

Munich, June, 1887.

PILOCARPINE POISONING.

To the Editor of The Medical News,

Sir: About five years ago I saw a case of pilocarpine poisoning which I never thought of sufficient importance to report until I had read the account of Dr. Glinsky's case, quoted in The Medical News of July 16th. The treatment being very different but the result the same, my case may have some value in connection with that

one. I was then a second-year medical student and my room-mate, a druggist, wishing to "break up a cold," asked my advice as to the best diaphoretic. Following my instructions he took two drachms of the fluid extract of jaborandi and went to bed. In about half an hour, when I followed him up-stairs, I found him suffering with the symptoms exactly as detailed by Dr. Glinsky—profuse perspiration and salivation, dimness of sight, prostration, a sensation of cold, tremors, and extreme general nervousness. I was too much frightened to take his pulse or temperature or note the state of the pupils. Comforting him with the assurance that I had never heard of any one's dying from the effect of jaborandi, I hastily consulted all the authorities at command, but without getting any help from them. While I was trying to decide what to do, all the symptoms suddenly passed off, excepting only the perspiration, which persisted, though in a moderate degree, for several hours. The duration of alarming symptoms was certainly not over an hour and a half, probably not more than an hour from first to last. No effect of the jaborandi was perceptible on the following day.

Dr. Glinsky's patient recovered promptly and thoroughly under the use of tannin, emetics, and atropine. Mine did equally well on nothing at all, and I think the suddenness of the improvement was as striking in my case as it could possibly have been in his. His treatment was rational and scientific, and, doubtless, under the circumstances, the proper thing to do; but that it was unnecessary, or, at least, that it would have been so in my case, I am sure.

EDWIN H. RIDWELL, M.D.

VINELAND, N. J., July 21, 1887

DANGERS OF ANTIPYRIN.

To the Editor of THE MEDICAL NEWS.

SIR: Your editorial in THE MEDICAL NEWS of July 23d on the "Dangers of Antipyrin," comes very appropriately at this time to me, having just had an experience in the use of antipyrin which impresses me with the fact that it is a dangerous drug, especially when there are idiosyncrasies.

A few days since I prescribed antipyrin in seven grain doses in the form of capsules to a lady in good general health suffering from nervous headache, the ordinary remedies having failed to relieve her. She took the first dose, and reported to me that in a short time, within five minutes, it had such a distressing effect on her that she said she feared she would die. Roaring in the head, watery and suffused eyes, burning sensations about the neck and face, and what was the most alarming symptom, great uneasiness in the præcordial region, a feeling of constriction and inability to breathe were the conditions noted. The effects gradually wore off and the headache was relieved. A few days afterward a second capsule containing seven grains was taken for the same purpose and with the same results, only more intensified, as she reported.

Some days ago I saw the lady, and telling me that she was suffering from a headache, I gave her, much against her will, one-half of the seven grain capsule, making grains iiiss. It was but a few moments until all the unpleasant symptoms above described were seen: suffused eyes, roaring in ears, with burning sensation over neck and face, and the most marked evidence of cardiac depression and embarrassed respiration. The pulse being so feeble and frequent, and the other signs of collapse so marked, I felt the urgency of stimulating, which was accordingly done. Gradually these effects wore off, the last of the unpleasant symptoms to disappear being the constriction in the præcordial region. While recognizing antipyrin to be a valuable addition to the list of our new remedies, we cannot be too cautious in its use. I can but think that the dose ordinarily advised is too large.

Yours, etc.,

ALEX. H. WEIR.

WESTERN LUNATIC ASYLUM,
STAUNTON VA., July 23, 1887

NEWS ITEMS.

A SANITARY CONVENTION will be held at Traverse City, Michigan, under the auspices of the State Board of Health, on Wednesday and Thursday, August 24 and 25, 1887.

THE NEW BRUNSWICK MEDICAL SOCIETY held its seventh annual meeting on July 19th and 20th, at St. John, Dr. P. R. Inches, of St. John, presiding. The following officers were elected for the ensuing year:

President.—Dr. P. R. Inches, of St. John.

Vice Presidents.—Dr. B. S. Thorne, of Havelock, and Dr. J. H. Ryan, of Sussex.

Treasurer.—Dr. Thomas Walker, of St. John.

Secretary.—Dr. T. W. Musgrove, of St. John.

CHROME YELLOW IN "NOODLES."—A Philadelphia baker has been recently arrested by the Society for the Prevention of Food Adulteration on a charge of coloring "noodles" with lead chromate. "Noodles" as sold by this baker are cakes, not unlike the American doughnut, but are German in their origin.

THE SALE OF HOMŒOPATHIC REMEDIES BY DRUGGISTS.—The Austrian authorities refuse to allow druggists to sell homœopathic remedies, but limit the dispensing of such articles to homœopathic practitioners who follow the laws of homœopathy. The purpose of the regulation is to check the sale of proprietary preparations.

FRENCH AMBULANCE TRAINS.—The Railway Company of the West has recently equipped a model train for the transportation of sick and wounded soldiers, in time of war or of mobilization. It is so arranged that in time of peace it may serve the ordinary uses of transit; when a hospital train it will be under the care of the Red Cross Society.

The train in its different cars, when ready for use, will represent a well appointed hospital, with all the equipments for food, drugs, surgical supplies, and attendance which ingenuity can suggest. The apparatus for the easy support of the sick and wounded is also of the best.

THE SANITATION OF HEALTH RESORTS.—In a paper on the sanitary police of watering places and health resorts in France, presented to the French Society of Public Health, Dr. Bouloumie explains briefly why it is

that the present system of inspection and supervision of these plans, which in theory is quite elaborate and careful, amounts to nothing in practice.

The chief object of the local medical inspector or health officer at such a place is to get practice among the visitors, and to obtain this he needs the good will of the proprietor, the hotel-keeper, etc. He must be prepared at all times to certify to the excellence of the sanitary arrangements, to prove that the water is good, the sewerage superb, and that any alleged cases of typhoid are either not typhoid or have been contracted elsewhere.

It is, of course, quite different with the physicians of our own health resorts, but perhaps it will tend to keep them thoroughly conscientious and disinterested in their opinions if sufficient scepticism be maintained to demand additional evidence as to the healthfulness and sanitary condition of these places of public resort. We observe that even State boards of health are sometimes very reluctant to tell the truth to the public about the health resorts which are under their jurisdiction, so that it is no wonder that local health officers should lean—just a little.—*Sanitary Engineer*, July 9, 1887.

Professor Kölliker, of Würzburg, recently celebrated his seventieth birthday and fortieth anniversary of his academic work. He was the recipient of distinguished honors, and the occasion was made by his friends and students a festival of three days' duration.

Luminous Paint in Theatres.—Herr Stehle, the Government Inspector of the Royal Bavarian Court Theatre, has, according to *Iron*, given high testimony to the use of luminous paint as a safeguard against panic in theatres. Any explosion or disaster with gas leaves the exit passage of the theatre in total darkness, and even if additional oil lamps were used, they would probably be extinguished by the air concussion. In the above-named theatre inscriptions in luminous paint are suspended over the exit passages, which direct the audience to the "way out" (*Ausgang*). "These placards, in spite of being exposed to the very poor light of the corridors in the daytime and the gaslight in the evening, are so luminous after the gas has been turned out that anyone can gain the stairs in each corridor without difficulty." The precaution is so simple and inexpensive that we wonder it is not immediately adopted in all theatres. Indeed, we see no reason why its use should not be made compulsory. Surely some provision of this kind might be included in the Theatres Bill now before Parliament.—*Lancet*, May 14, 1887.

Flavoring Extracts—Are they Poisonous?—Cooks, confectioners, and others engaged in the preparation of foods and drinks are in the habit of using various artificial perfumes, which in chemical language are such bodies as amylic valerianate, amylic butyrate, ethylic butyrate, propylic ether, and caprylic alcohol. The odor and flavor of the apple, the pear, the pineapple, the strawberry, and the raspberry can thus be imitated. These imitations not only remove the necessity for the use of the natural fruits, but are less expensive, and, besides having perfect similitude with them, give the appropriate flavor in a more accentuated form. MM. Poincaré and Vallois have sought to ascertain whether these artificially prepared perfumes possess poisonous properties by injecting them under the skin of animals, as well as introducing them into the stomach. Dogs and guinea-pigs can withstand even large doses of these substances when injected under the skin; but these animals can be poisoned by sufficiently large doses, and then the symptoms set in rapidly. The most constant toxic symptom was great prostration, which was followed in a variable time by coma. These phenomena were less marked in the dog than the guinea-pig. All the animals were troubled with violent nasal irritation and sneezing, and distressed breathing was always evidenced by overaction of the respiratory muscles. An excessive secretion of mucus from the bronchial tubes was also noticed. Notwithstanding the gravity of the symptoms, the majority of the animals recovered. The practical outcome of these experiments is to sanction the use of infinitesimal doses such as are already employed for artificial flavoring of aliments.—*Zymotechnic Magazine.*

Trespassing Practitioners.—The *New York Medical Journal* of July 16, 1887, thus surveys the field of medicine, in which the medical men of different countries show a disposition to overstep limits prescribed by national boundaries:

The Chicago *Inter-Ocean* having complained, rather unnecessarily, we think, that the Canadians do not recognize American degrees as a title to practise in the Dominion, the Canada *Lancet* publishes a very judicious editorial article in which it sufficiently explains that in this fact there is no real occasion for ill feeling. It carries its frankness so far as to acknowledge that the better American schools are superior to those of its own country, but it adds, quite correctly, that there are other American schools which are so far below the Canadian standard that, without an invidious distinction being made, it is impossible for the Canadians to register American practitioners on the mere ground of the degree. On the other hand, the *Medical Press and Circular*, of London, grumbles about the number of German doctors who make incursions into the United Kingdom for the purpose of drumming up remunerative practice. Whereupon the *Deutsche Medizinal-Zeitung* pointedly remarks: "Und Mackenzie?"

Hypnotic Exhibitions Forbidden in French Theatres.—The municipal authorities of Bordeaux have forbidden the public exhibitions of two hypnotizers in one of the theatres of the city. The occurrence of accidents to those hypnotized occasioned the action.

Artificial Climates for Invalids.—In the belief that modern science can command climate, Dr. B. W. Richardson proposes that British invalids be given in their native isles the winter advantages of tropical resorts. This he would accomplish by establishing winter homes, or health palaces, each containing fifty or more comfortable two-story houses, enclosing a large square of ornamental grounds, and provided with libraries, baths, gymnasia, amusement halls, etc. Flower-lined galleries, giving long promenades, would extend over the houses under glass roofs, while the central enclosure would be shut in by an immense arch of glass at a great height above the ground. Suitable heating and venti-

lating apparatus would give an equable and adjustable temperature to all parts of the structures, and any desired character might be imparted to the climate. Even cloudy days need not be known, as electric suns could be made to shine at pleasure. In many places winter resorts on a grander scale might be created by putting whole valleys under roofs of glass, forming parks of constant beauty and healthfulness.—*American Analyst*, July, 1887.

MORTALITY AT THE PANAMA CANAL.—When this gigantic undertaking, which is gradually approaching completion, is finished, the medical history of the undertaking ought to be written. A statement was recently made, on apparently good authority, to the effect that the annual mortality amounted to the appalling percentage of 60 for the colored laborers and 80 for the white. These figures are very much greater than are justified by statistics, for, according to an official document recently published, the average annual mortality on the works does not exceed 10 per cent., but even this figure is fearfully high. Probably very few enterprises in modern times have proved as fatal to the men engaged as this one, a result which is attributable to the extremely unhealthy nature of the climate and also to the insanitary conditions under which these large aggregations of men have had to live. The mortality at the commencement of the excavations was still higher, but the company has recently become alive to the fact that this high rate of mortality is very expensive, and have, therefore, taken some steps to render the dwellings and manner of living of the men less prejudicial to health and life. Unfortunately the disease and mortality statistics of such undertakings are almost invariably kept in a very perfunctory style. It would have been very instructive to have had some information with respect to death from disease and accident among the men employed in carrying out the recent metropolitan improvements. It would probably have been made apparent that the soil of old cities like London cannot be disturbed on a large scale without a corresponding tribute of mortality. The tunnel which is shortly to be driven beneath the Thames offers an excellent opportunity for the collection of precisely this kind of information.—*British Medical Journal*, July 9, 1887.

A VETERAN ANATOMIST.—On April 30th, at 11 A.M., the Anatomical Theatre of the Imperial Medico-Chirurgical Academy of St. Petersburg was the scene of a lively and noteworthy gathering of physicians, surgeons, students, and deputies from numerous learned societies, lay and medical, from every part of Russia, to congratulate Professor Wenzell Gruber upon his having held the professorship of practical anatomy for no less a period than twoscore years. During that time Dr. Gruber, besides having instructed, examined, and passed 8000 medical students in practical anatomy, has himself dissected, or superintended the dissection of, upward of 30,000 bodies. His talents, when Hyrtl's demonstrator in Prague (from 1844 to 1847), having been noticed by the late Prof. Pirogoff, he was invited by the eminent Russian surgeon to St. Petersburg, where he at once received the appointment of Demonstrator of Anatomy at the Imperial Medico-Chirurgical Academy.

From various parts of the world there were eighty telegrams sent to the veteran anatomist, while upward of twenty gorgeously illuminated and bound addresses from different societies congratulated him on the completion of his fortieth year of professorship. A large gold medal, struck in his honor, was presented to him, while a copy of it in silver was struck for and presented to Mrs. Gruber. On one side of the medal are the Christian and family names of Gruber, and below a very good likeness of him; the finely shaped oval head, the high and full brow, the thick, bushy head of hair, and the rounded and beautifully chiselled chin are admirably portrayed by the sculptor. The reverse of the medal presents, in its centre, the large Roman numerals XL.; below the inscription is 1847–1887; while above is written: "To the teacher of 8000 Russian surgeons." A splendid album, containing upward of sixty original paintings in oil and water-colors, was presented to him by some of the first artists in Russia. The emperor created him a Knight of the White Eagle, one of the highest of Russian orders. Indeed, there was no end of telegrams, addresses, memorials, and speeches—all tending to show how deeply respected and beloved Gruber is, alike by colleagues, pupils, and the public in general. So remarkably prolific a writer is Gruber that during forty-three years, the number of his published anatomical memoirs and pamphlets exceeds 540—a proof that the anatomists of a bygone age were generous enough to leave something for their followers to do and discover.—*Lancet*, July 9, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JULY 26 TO AUGUST 1, 1887.

MAGRUDER, D. L., *Colonel and Surgeon.*—Granted leave of absence for one month, to take effect on or about August 10, 1887. *S. O. 170, A. G. O.*, July 25, 1887.

MCCLELLAN, ELY, *Major and Surgeon.*—Detailed as a member of a board of survey, to meet at the Medical Purveying Depot, St. Louis, Mo., on August 1, 1887.—*S. O. 173, A. G. O.*, July 28, 1887.

CALDWELL, D. G., *Major and Surgeon.*—Order relieving him from duty at Fort D. A. Russell, Wyoming Territory, and assigning him to duty at Fort Assiniboine, Montana Territory, is revoked.—*S. O. 168, A. G. O.*, July 22, 1887.

CLEARY, P. J. A., *Major and Surgeon.*—Ordered to Fort Assiniboine, Montana Territory, instead of Fort D. A. Russell, Wyoming Territory.—*S. O. 168, A. G. O.*, July 22, 1887.

BURTON, H. G., *Captain and Assistant Surgeon.*—Sick leave of absence extended three months.—*S. O. 171, A. G. O.*, July 26, 1887.

GARDNER, E. F., *Captain and Assistant Surgeon.*—Ordered for duty at Fort Keno, Indian Territory.—*S. O. 170, A. G. O.*, July 25, 1887.

MCCAW, W. D., *First Lieutenant and Assistant Surgeon.*—Ordered for temporary duty at Fort Riley, Kansas.—*S. O. 78, Department of Missouri*, July 25, 1887.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

VOL. LI. SATURDAY, AUGUST 13, 1887. No. 7.

ORIGINAL LECTURES.

ON SOME OF THE PROBLEMS TO BE SOLVED BY PHARMACO-PHYSIOLOGY,

WITH A NEW OUTLINE CLASSIFICATION OF PHARMACOLOGY.

A Lecture

Delivered before the advanced class of students in physiology in the Biological Laboratory of the Johns Hopkins University, May 9, 1887.

BY H. G. BEVER, M.D.,

PASSED ASSISTANT SURGEON, UNITED STATES NAVY; FELLOW, BY COURTESY, OF THE JOHN HOPKINS UNIVERSITY.

GENTLEMEN: In response to an invitation to speak before you on some of the problems to be solved by experimental physiology, I have selected the subject of the physiological action of drugs, not only because it has interested me for a number of years, but also because it is one which will illustrate to you better than any other some of the applications of that experimental science, in the practice of which you are now being drilled and educated.

The study of the physiological action of drugs, however, forms but a part of experimental pharmacology; and, therefore, before proceeding to treat of the special subject of this lecture I have deemed it most desirable, for several reasons, to say a few words with regard to pharmacology in general.

I do this not merely for the purpose of calling your attention to the important position which pharmacology itself has assumed within late years among other sciences, but also in order to enable you better to understand and realize the close and intimate connection which exists between it and physiology, as well as other sciences, with which it is more or less intimately connected.

The term pharmacology conveys, perhaps, to some of you but a vague, indefinite idea of a certain knowledge of drugs, and their action upon the animal organism, necessary though it be for the physician to possess, otherwise of very little general interest. I hope, however, to convince you that pharmacology, in the widest sense, is not only a necessary accomplishment of the physician, but also that it is full of interest to the general biologist.

Being largely dependent on chemistry and physiology, as a separate science, it must naturally be looked upon as of rather recent date, though its name is as old as that of medicine itself. Unlike other sciences, it cannot be considered a simple outgrowth of one mother science, or as a more highly specialized branch of any one single science, as, for instance, pathology is in its relation to physiology, or, as the latter may be regarded, an offspring of anatomy; but, on the contrary, it includes and harmoniously unites several of these, making them all subservient to its peculiar end.

The classifications and subdivisions of pharmacology which we find in some of our best text-books even at the present day can, in our opinion, hardly be looked upon as at all satisfactory, much to the disadvantage of both teacher and student, but especially the latter. As pharmacology is increasing more and more in importance, a more concise and comprehensive classification and subdivision of this subject is becoming with every day more and more of a desideratum.

Having had under my charge the National Collection of Drugs at Washington during the past three years, which is perhaps the most extensive and complete collection of any we possess in this country, and having, besides, been more or less actively engaged in the investigation of the action of drugs during the same period, the question of the desirability of a new classification has frequently forced itself upon my mind, and a very puzzling one it is, too. Much might be said as to the advantages and disadvantages of the old standard division of the subject into materia medica and therapeutics, or that into pharmacology, materia medica, and therapeutics; but, without taking up your time in criticising the old, allow me to invite you to look at a new one.

This classification seems to me a considerable improvement over the old, and would, if accepted, undoubtedly do much to bring order into what, it may be said, is chaos now. The latter is more especially true for the minds of the students of this department of medicine.

Beginning with the definition of the term pharmacology itself, I need scarcely remind you of the fact that it is a word, like a great many others, which has been derived from the Greek, and simply means a knowledge of the substances known as drugs and employed as remedies. This term forms a very happy expression for the subject under consideration, and is consequently retained in this classification, as including everything relating to the subject.

The first great subdivision of pharmacology into (1) descriptive, and (2) experimental, is, I think, equally natural, expressing, as it does, the two mainsprings from which all our knowledge is derived, and as indicating, at the same time, the two main lines along which pharmacology must be studied and extended.

Since all those substances which ordinarily we call remedies are derived from either of the three natural kingdoms, descriptive pharmacology, furthermore, might be conveniently treated of under the three following heads, namely: Pharmaco-mineralogy, pharmaco-botany, and pharmaco-zoölogy. By descriptive pharmacology, and, as is indicated by the terms of its three subdivisions, we would, therefore, include not only a superficial acquaintance with the mere external or physical characteristics of the drugs derived from these three sources, a branch of pharmacology hitherto designated by the term pharmacognosy, but a more profound knowledge of the significance of the princi-

ples of mineralogy, botany, and zoology in their relation to those substances which are derived from them.

I will illustrate what is meant by these terms by defining very briefly the term pharmaco-botany, choosing this one because it forms the best example, and most of the drugs now used are derived from the vegetable kingdom. I hold that without a knowledge of botany and its principles, or, in other words, the biology of plants, a sound knowledge of drugs is impossible. The mere enumeration of the outward appearances of roots, stems, leaves, and flowers, of the different plants which furnish us with drugs, may perhaps sound like music to some, but it is at best music without a soul or expression. It is still within my recollection when true roots, rhizomes and tubers were all included under the head of "radix," simply for the reason that they grew under ground. The fact that we now distinguish radices, rhizomata and tubera, I need not tell you is due to a study of their morphology, which distinguishes plainly and concisely one from the other; hence, it must be evident that without a knowledge of plant morphology, pharmacognosy is a mere mechanical accomplishment of the memory, and without a scientific basis.

We know, furthermore, that as we pass from the cryptogams on to the flowering plants, different, and at the same time characteristic chemical constituents are found, which are peculiar to the different classes and genera; and not only so, but each individual plant, in accordance with its different stages of development, contains different chemical constituents. The chemical constituents of plants, however, are the products of their physiology, which becomes more complicated and perfect in plants as well as animals as we pass from the lower to the higher orders. Hence, without a knowledge of plant physiology we should find ourselves without a guide as to what kind of substances we should expect to find in this or the other plant. Vegetable morphology and physiology are, therefore, necessary accomplishments of the pharmaco-botanist and the general pharmacologist.

The term "experimental pharmacology," forming the second main division in this classification, is here made to include all that knowledge regarding drugs which is derived directly from experiments made in the laboratory. The experiments, however, made with drugs in the laboratory, being of necessity either physical, chemical, physiological, or pathological, the four subdivisions of this part of our science into pharmaco-physics, pharmaco-chemistry, pharmaco-physiology, and pharmaco-pathology, seem to follow quite naturally.

Under the head of pharmaco-chemistry, it would seem desirable to include not only a knowledge of the means and methods by which drugs are obtained from their natural sources (pharmacy), but also a practical knowledge of the far more important and complex problems of analyzing these substances and ascertaining, so far as can be done at present, the chemical constitution of them, with the view of preparing them artificially, and of artificially altering their composition in accordance with the demands of pharmaco-therapy.

By "pharmaco-physiology," we mean to designate that part of pharmacology which deals with all those most intricate and important problems bearing upon the action of drugs upon the normal, living animal organism and its various parts; it has, furthermore, for its object the scientific explanation of such action; it is the greatest enemy of empirical pharmacology. The pharmaco-physiologist studies the relation which exists between the chemical constitution of a remedy and its physiological action, and it is in this field of investigation more especially, that we may look for the production of the most exact and the most important results in the near future. Without a knowledge of the chemical constitution and physiological action of those substances which we call remedies, their administration in disease cannot be said to rest on anything like a scientific basis, but must be purely empirical, and the good effect which, in some cases, it produces, must be looked upon more as a fortunate circumstance than a logical sequence.

By the term "pharmaco-pathology" it is intended to designate that branch of pharmacology which has to deal with the study of the action of drugs on the animal organism in a state of disease, and under this head both man and animals might be included. This division of the subject, therefore, is made to comprise both human and comparative pharmaco-pathology, and its laboratory is the hospital.

From what has been said, it is evident that the practical or experimental pharmacologist must be master, at least to a certain extent, of chemistry, physiology, and pathology; that his laboratory, to be complete, must be equipped with chemical and physiological apparatus, and be in close intimate relations with a well-organized and well-disciplined hospital and, if possible, also with a hospital for the treatment of the diseases of the lower animals. It is and must be admitted that the administration of drugs in disease, even in this enlightened age, is to a large extent still experimental, and that part of it, which cannot be called experimental, is empirical. Those who would reject as inhuman, experiments with drugs on the lower animals, would indeed do well to remember that they themselves at any moment, and quite unknowingly, may become the willing victims of such experimentation at the hands of much more ignorant experimenters than are usually allowed to engage in such experimentation on frogs, rabbits, and dogs. The pharmaco-pathologist, therefore, studying the action of drugs principally upon man in a state of disease, performs the most responsible part of the duties of the general pharmacologist. He should, accordingly, undertake his part of the task only with the aid of all the light which chemistry and physiology have already thrown upon the nature and action of the remedy which he is about to administer, with the final aim of relieving human suffering, or even with a view of saving valuable human lives.

There are, however, also remedial agents, such as electricity, heat, cold, water, climate, condensed and rarefied air, gymnastics, and massage, which are of considerable importance in the treatment of disease, and a classification of the subject of pharmacology, claiming to be complete, cannot afford to set these aside. These being mainly physical agents, I have thought it best to include them all under the term pharmaco-physics.

There still remains to be defined that most august term, "pharmacotherapy," or, the science of curing disease by means of remedies. What shall we do with it? Up to the present we can hardly speak of pharmacotherapy as being more than an ideal; it is a science of

the future much more than of the present, to be established by experimental pharmacology. It will not be until experimental pharmacology has placed in our possession a much more accurate knowledge of the chemical nature, and of the action of drugs, in both normal and pathological states, that we have any right to claim as ours the knowledge of the cure of disease by means of remedies. Pharmaco-therapy, as indicated by our classification, is applied pharmacology, it is the practical outcome of the latter, and, although the result of experimental pharmacology, it is itself, or should be, placed *beyond the range of experimentation.*

To sum up briefly, pharmacology may be said to have for its purpose the study and investigations leading to a perfect knowledge of drugs and their actions; the mineral, vegetable, and animal kingdoms are the natural sources from which these are derived; physics, chemistry, physiology, and pathology are the means which it employs in the determination of their properties and pharmaco-therapy, or the knowledge of the cure of disease by scientific methods, is its great aim and end.

Pharmaco-physiology, then, according to the definition above attached to this term, has for its object the scientific study and investigation of the action of drugs on the normal living animal organism and its various parts.

It would, of course, require a whole course of lectures to treat of this subject in an exhaustive manner, and I have only time to speak of a few of the more important problems which are now before the pharmaco-physiologist. One of these, no doubt, is the study of the relation which exists between the chemical constitution of certain substances and their physiological action.

Assuming that you all know, more or less, of the fundamental principles upon which rests our present classification of the elements into definite and related groups, and that you are, furthermore, acquainted with the circumstances which led to the discovery of the metals gallium, germanium, and scandium, which were all accurately described by Mendejleff before being discovered to fill a certain gap in a group, it must likewise be the great and final object of the pharmacologist to obtain such a knowledge of the existing relations between the chemical and physical characters of substances, and their actions upon the living organism that we may be able to predict their actions with certainty.

Mercury and calcium, at first sight certainly, do not resemble one another very much, and yet it has been shown by Provost that in acute poisoning by mercury, the calcareous matters disappear from the bones and in the process of elimination by the kidneys, produce calcification of these organs.

We find that each element and each of its various compounds has chemical reactions special to itself by which it can be recognized and distinguished from all others. The number of these chemical reactions is, therefore, very large, but there are a few which are common to a large number of the elements.

We shall find that something similar occurs in their physiological reactions, just as we can divide and subdivide the elements and their compounds into groups and subgroups by a careful study and comparison of their chemical reactions, so we may also divide and classify drugs according their physiological reactions.

In the language of Dr. Lauder Brunton, the physiological reactions which occur between the elements and their compounds and the tissues of the body can be subdivided into large groups. Thus, we find that a very large number of substances, when used in large quantity paralyze muscles and motor nerves. This large group may again be subdivided into those which paralyze muscle while affecting the nerves but slightly, and those which paralyze the nerves and leave the muscle uninjured.

Another large group is that which acts especially on nerve-centres, and has little effect either on muscle or motor nerves. This group contains subgroups of substances which affect the brain, medulla, or spinal cord by exciting, paralyzing, or disturbing their functions.

Another group is that which chiefly affects the circulatory organs, and still another that which influences the secretions, with subgroups of substances affecting more particularly the secretory activity of the sweat glands, mammary glands, the salivary or intestinal glands, the liver, or the kidneys.

As a very striking instance and as one well calculated to impress upon you the intimate and, at the same time, important relation between physiological discoveries and pharmacological progress, I may cite the following, viz.: Those of you who have lately had the good fortune of listening to the very interesting lectures given in this laboratory by Dr. W. H. Howell, on the subject of "Secretion," are well acquainted with the brilliant results obtained by Heidenhain and his pupils as regards glandular function. Based mainly on these recent advances in physiological science, pharmacologists, it seems to me, are already beginning to turn their attention to the study of the action of drugs upon glandular activity, and some far-reaching results in this line of research may be looked for in the near future. For instance, it is a fairly well-settled question in physiology that the epithelia lining the convoluted tubules of the kidneys are the structures principally concerned in the excretion of the solid constituents of the urine, and that the epithelium lining or covering the glomeruli is the tissue chiefly engaged in the secretion of the watery constituents of the urine; blood pressure, *cæteris paribus*, taking a subordinate position to cellular activity and not a primary one as was formerly supposed to be the case.

Dr. von Schröder, of Strassburg, Germany, in a beautiful series of experiments, has succeeded in conclusively demonstrating, at least to my mind, the fact that caffeine, injected into the circulation, gives rise to a much increased flow of normal urine. From our knowledge of the physiological activity of this organ and his experiments, there is but one conclusion possible, and that is, that caffeine, in some way, exercises a stimulatory influence upon the epithelial lining of the convoluted tubules, and perhaps also that lining the capsule.

A number of questions at once arise, and since they attach themselves almost naturally to the one under consideration, we cannot do better than discuss a few of these, inasmuch as they seem to me particularly well intended to illustrate to you the kinds of problems which the pharmaco-physiologist has to solve, and the close and intimate relation they bear to physiology.

Although I have, as yet, seen no reference made to any of these which will here be mentioned, they must

necessarily of use to any one who thinks at all on what he reads. So far as is known up to the present, renal secretion is not excited by the stimulation of any nerves which would correspond to the so-called secretory nerves in other glands; and the kidney, therefore, differs in this respect from the salivary and sweat glands, both of which can be excited to functional activity by the stimulation of certain efferent nerves.

We must now ask ourselves: Does caffeine affect these glands similarly? and if so, how does it do so? If it does so, does it effect its results by influencing secretory nerve structures, or does it produce increased secretion through its direct action on glandular epithelium? In case that caffeine should be found to produce an increased flow of saliva by either stimulating secretory nerve-structures or the glandular epithelium, have we here a possible argument in favor of the presence of secretory nerve-fibres in the kidneys?

Again, atropin puts a stop to the secretory activity of salivary glands, because, as we say, it paralyzes the terminations of the secretory nerves in these glands, and the question at once arises, in consideration of the above facts, Does atropin have the same effect upon the kidney? and if not so, would we here have an argument in favor of the absence of secretory nerves in these organs?

All these are questions of vital importance, and must be and will be answered in the near future by some one; they well illustrate the nature of those problems which the pharmaco-physiologist has to deal with, as well as the intimate relations existing between himself and the physiologist.

There are perhaps objections made by some to the results obtained by von Schröder. There are, as a rule, many more objectors than experimenters, and if there is any possible fault or flaw in von Schröder's method of experimentation, let us see what it might be, for sooner or later we will be called upon to answer such objections. Von Schröder tells us that he chloralized his rabbits before he injected his caffeine, in order to eliminate as much as possible the stimulating influence of caffeine on the vasomotor centre in the medulla. According to experiments by Binz and Mayer, chloral, trichlor-acetic acid—in fact, all easily decomposable halogen derivations of certain organic substances—by setting their chlorine, bromine, or iodine free, depress, or, for the time being, may even totally paralyze cellular activity. From this influence, according to Binz and Mayer, neither vegetable nor animal cells are exempt. It is evident, therefore, that, providing Binz and Mayer are correct, the results obtained by Schröder may be misleading. In my opinion, these objections if even they are well founded, would impair the value of von Schröder's results in a certain degree only. All that can be maintained against them is, that his standard of comparison is a subnormal rather than a normal one, while the interesting and principal fact remains, namely, that caffeine arouses the renal epithelium to activity, whether it be in a normal or subnormal condition at the time of its exposure to the influence of caffeine.

The physiological action of any drug depends, to a great extent, not only on its general affinities for certain classes of tissues, but also upon its peculiar affinity or power of acting on one tissue or organ first, and the organ thus affected, through its functional activity, being modified, may greatly alter the effects of the same drug on others.

As a very good example of this we may take the effects produced by very large and moderate doses of veratrine on the frog. A moderate dose will produce great stiffness of the muscles, while a very large dose may have comparatively little effect. Yet, if the large dose were applied directly to the muscles, it would act more powerfully than the moderate dose. The reason why it does not do so in the living body is, that the circulation stops; and, therefore, the poison not being conveyed to them, has no action on the muscles.

With regard to the relation existing between atomic weight and physiological action, we have as yet no very clear conception, so far as the results attained from experiments in that direction allow us to judge. There is, however, a field opened to the investigating pharmacologist which, as experiments tend to show, is promising of great results, and this consists in the study of the relation which exists between chemical constitution and the physiological action of certain substances. It has been shown by the discoveries of Crum Brown, Fraser, and Schraff, that by artificially modifying the chemical constitution of a drug, it is possible to modify also its physiological action, and that similar modifications in chemical constitution induce similar modifications in the action of their derivatives. Thus, they have shown that by introducing methyl into the molecule of strychnine, brucine, and thebaine, the convulsive action exerted by these substances on the spinal cord was changed into a paralyzing one exerted on the ends of the motor nerves. Besides these, other alkaloids which ordinarily do not exhibit a convulsive action, exhibit a paralyzing one when their constitution is modified by the introduction of methyl into their normal constituent molecules; thus, methyl-morphine, methyl-nicotine, methyl-atropine, methyl-quinine, and methyl-veratrine, and several others, all exhibit this paralyzing action. A number of experiments made with regard to this point by Drs. Lauder Brunton and Cash seem to show that, as a general rule, most of the compound radicles formed by the union of amidogen with the radicles of the marsh-gas series possess a paralyzing action on motor nerves.

The subject of the relation between chemical constitution and physiological action is at present one of the most important problems to be solved in pharmacology. Already many of the most important alkaloids, derived ordinarily from the vegetable kingdom, have been produced artificially in the laboratory, and their chemical constitution has been studied with results more or less satisfactory in the different cases. Thus, for instance, caffeine has been found to be a tri-methylxanthin. Hydroxyl, methoxyl, and ethoxyl have been introduced, and characteristic changes in the action of the resulting compounds have resulted. Filehne, in experimenting with hydroxy-caffeine, found that it required nearly twenty-five times the dose to produce the rigidity of the muscular system of the frog that it did when unmodified caffeine was used, and that the dihydroxy-caffeine produced no effect whatever on the muscular system. The physiological action of ethoxy-caffeine seems no less remarkable, for, instead of producing rigidity and tetanic spasms, it seems to have the directly opposite effect, namely, that of producing diminished reflex ex-

citability, and in the higher animals, rabbits, and man, sleep and intellectual torpor are produced.

These modified caffeines have already been made use of in pharmaco-therapy, and a number of cases already stand recorded in which painful neuralgias of various parts of the body have been successfully treated by means of them.

The chemical study of drugs and their artificial production in the laboratory have, however, another important advantage, more especially for the physiologist. The explanation of the normal action of a highly complex alkaloid upon a still more highly complex and complicated organism, has at all times been the greatest difficulty in the way of the pharmaco-physiologist. Most of our difficulties to explain aright the manner of action of substances on the animal organism, are directly traceable to this double complexity. And yet there is, perhaps, no question that I have been asked more often in connection with my own investigations, and by men of very high standing in the medical profession, than the one, Why do you isolate your organs, and why do you want to split up your alkaloids?

It is not too much to say that, among the many drugs which we possess and administer in large quantity every day to a host of suffering invalids, there are, even in this enlightened age, scarcely half a dozen the physiological action of which is at all well understood, and perhaps not one on the nature of the action of which there is no doubt whatever left. This is evidently due to nothing else than the very complex constitution of the remedies employed, and the many possibilities of their acting on this or that class of tissues with greater or less affinity than on others. Hence, the great tendency of the present day; and, in fact, the only way left open to us as investigators of this line of research out of the difficulty is, first, the simplifying, as far as that can be done, of this great living machine into its constituent organs and tissues—in other words, the successful isolation of these organs from the rest of the body and the keeping them alive for a certain length of time, and, on the other hand, the simplification of the drugs and substances the action of which is to be ascertained.

It is for these very potent reasons that the successful isolation of any organ of the body without impairing, at least for a time, its normal functional activity, must be looked upon as a most important and fortunate step in the direction toward the solution of a multitude of physiological as well as pharmacological problems which could otherwise never have been even approached. And so, also, the simplification of those substances which we must recognize as highly complex into their constituent residues or molecules, must be looked upon as of parallel importance.

For the purpose of rendering this question a little clearer, we will take the case of atropine. From the large number of experiments made with this drug we have now abundant proof of the multiplicity of tissues that are influenced by it and also of the complexity of its action on any one organ or tissue. Confining ourselves to the action of atropine on the nerve terminations in certain viscera, we have, furthermore, very good proof that it affects two kinds of nerve structures simultaneously and similarly. The organs, like the heart, the pupil, and the intestines, which have been shown by Gaskell to be supplied by two classes of efferent nerves namely, motor and inhibitory, we have evidence of atropine stimulating and finally paralyzing both these structures.

This fact, however, could only be rendered capable of solution by a study of the action of atropine on isolated organs. The question now arises, Can we still further prove by much more accurate experiments than have been made hitherto, that atropine really affects both motor and inhibitory nerve-fibres?

We will see!

Some years ago Kraut and Lossen succeeded in splitting up the alkaloid atropine into tropine and tropic acid. Lossen more especially succeeded in showing that the decomposition mentioned went on according to the following equation:

$$C_{17}H_{23}NO_3 + H_2O = C_8H_{15}NO + C_9H_{10}O_3.$$

Ladenburg, in 1881, finally succeeded in producing atropine by synthesis from tropine and tropic acid by first neutralizing a solution of tropic acid with tropine, thus producing tropine trobate, and then boiling this compound with a small quantity of hydrochloric acid. The result of this procedure was a substance absolutely identical with atropine obtained in the natural way in all its chemical as well as physiological properties. The chemical identity was established by Ladenburg himself, the necessary physiological experiments were made principally by Profs. Hensen and Falck, who found, among other results, that the artificial drug antagonized muscarine stand-still of the heart, dilated the pupil, etc., in every way as the natural substance did.

According to the same method, Ladenburg undertook to manufacture certain other so-called semi-artificial atropines, called by him tropeines, in which the tropic acid molecule was replaced by a molecule of some other suitable acid.

Without going into a detailed account of the chemical and physiological properties of all these tropeines, it suffices for my purpose simply to call your attention to the important fact that with the substitution of tropic acid by other acids, went hand in hand a change in the physiological effects of the resulting compounds. Experimenting principally on the pupil, Hensen, Falck, and Volkers found that in most, if not all, tropeines dilatation was either not at all produced or very slightly so in comparison with atropine.

It was, therefore, not unreasonable to suppose that there exists a certain relation between this molecule and its physiological effect of dilating the pupil. According to Gaskell, moreover, the dilatation of the pupil is the result of stimulation of certain dilator fibres belonging to the class of inhibitory nerve-fibres, the innervation of the pupil being, in fact, similar to the innervation of the heart, the viscera, etc., and the question at once arose, Is the dilatation of the pupil by atropine due to the action upon these dilator fibres of the tropic acid molecule contained in atropine? and if so, Does this molecule similarly affect other nerve-structures, the histological structure and physiological function of which are identical with those of the dilator fibres of the pupil?

To investigate this point was the object I had in some experiments made in this laboratory during the last month.

The pupil did not seem to me a satisfactory organ of

the experimental investigation of this problem, and I, therefore, concluded to try the bloodvessels.

Through the kindness of Prof. Remsen, I was able to interest Mr. Lengfeld in the work, and he kindly consented to split up some atropine for me, into tropin and tropic acid. In the experiments on the bloodvessels, tropin was used in the form of the hydrochlorate; and the tropic acid as sodium tropate. Suffice it to say here, that it was found that sodium tropate caused vaso-dilatation, while tropine hydrochlorate gave rise to vaso-constriction. We have here, then, another very good example illustrative of the manner in which pharmacological problems must be solved, and, also, of the close relation which must always exist and be kept in mind, between chemical constitution and physiological action.

FORMS OF TYPHOID FEVER SIMULATING REMITTENT MALARIAL FEVER.[1]

BY I. E. ATKINSON M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF CLINICAL MEDICINE IN THE UNIVERSITY OF MARYLAND.

THE diagnosis of typhoid fever is often attended with especial difficulty in malarious localities, where it may closely simulate remittent malarial fever. Nearly all physicians practising where malaria prevails, are in the habit of treating cases that differ in important particulars from each of these affections, and yet present certain combined features of both. These cases are usually observed during the late summer and early autumn months, when both typhoid and remittent fevers most prevail. The concurrence of these two fevers had long ago been observed, but since the coining of the term "typho-malarial fever" by the late Dr. J. J. Woodward, in 1863,[2] our medical literature has been rather unduly burdened with its consideration.

It is hardly worth while to-day to discuss "typho-malarial fever" as an integral affection; even Dr. Woodward seems to have been misunderstood in his original definition of its nature, for at the International Medical Congress of 1876 he declared the term to be "conveniently applied to the compound forms of fever which result from the combined influence of the causes of the malarious fevers and of typhoid fever."[3] It must be conceded that this combination of the two specific poisons is frequently observed, but at the same time there can be no doubt that the widespread adoption of Dr. Woodward's terminology has not been advantageous, either to the study of the diseases involved or to their therapeusis: for upon the one hand there is encouraged an indolent consideration of their complex symptoms, and upon the other a tendency to treat the malarial at the expense of the typhoid elements of the disorder, usually to the decided disadvantage of the patient.

It is not my object in this paper to consider that aspect of the question in which the characteristic symptoms of typhoid fever exist in combination with equally characteristic symptoms of remittent malarial fever. It is at once granted that malaria may influence typhoid fever, just as it may modify pneumonia, dysentery, and other acute affections. Nor is it my purpose to refer more than briefly to those conditions occurring in malarious regions, where at the outset symptoms of remittent fever predominate, and not until later give place to the characteristic symptoms of typhoid fever, and but too frequently lead to the disingenuous diagnosis that a remittent has become transmuted to a typhoid fever.

Nor shall I engage in the discussion of that view of the subject that finds its most distinguished exponent in Loomis, and that denies to typhoid fever any part in the morbid processes that have received wide recognition as "typho-malarial fever," and ascribes them to a combination of a malarial and a septic element, under the title of "continued malarial fever," further than to claim that the history, course, symptomatology, and pathology of the affection so closely resemble those of typhoid fever that it is impossible to indicate any feature differing from those of the latter affection to an extent greater than can be accounted for by a complicating malarial element; and, furthermore, that the term "sepsis," in this connection, has not sufficient definiteness. Within limits it may satisfactorily account for anomalous cases in given localities, but it is impossible that such a septic influence should be so widespread as to produce the conditions under consideration, and yet fail to make itself manifest in other than malarial patients.

Finally, I shall not discuss the theory that "typho-malarial fever" is essentially malarial, a theory that has recently received support in Great Britain, and according to which it is a form of malarial fever in which intestinal and adynamic symptoms predominate.[1]

Tempting as these subjects are, they are considered from such different standpoints, and represent such differences of opinion, that one can at present hardly hope to reconcile them. One point, at least, is apparent: "typho-malarial fever," hybrid as it is, is far from including any definite pathological series, but is made to serve as the limbo into which writers crowd many groups of atypical cases. The object of the present paper is to direct more especial attention to a class of cases of continued fever in which the absence of nearly all characteristic symptoms except the fever has influenced medical men in malarious districts, at least, in assigning them to remittent malarial fever, and not to typhoid fever, to which disorder they properly belong.

Such cases are commonly encountered during the late summer and early autumn, though no season is without them. Beginning abruptly with slight chill, or insidiously, they run the course of remittent fever of mild type, either with slight variation of temperature, or of greater intensity with well-marked remissions, never passing into a typhoid condition, never developing the characteristic symptoms of typhoid fever, yet absolutely uninfluenced in their duration by anti periodic treatment, running a course of three, four, or even five weeks, and terminating almost invariably by slow lysis and recovery.

[1] Squire: Lancet, 1887, I., 73. Jagoe: Ibid., 1887, I., 119.

These cases are at first almost always regarded as of remittent malarial fever. From beginning to end they may develop no symptom that could not belong to this disorder, except the persistence of fever under strongly anti-malarial treatment, and the occasional concurrence of circumstances that point to a typhoid origin. There is no intellectual cloudiness or hebetude of expression. Sleep is but slightly disturbed. The tongue remains moist and coated with a thin whitish or yellowish fur; the appetite persists very often in some degree. There is almost never epistaxis. Constipation is commonly observed, diarrhœa very rarely. There are no bloody stools, no tympanites, no iliac tenderness or gurgling. Rose-spots are much more often absent than present. The patient can be restrained in bed with difficulty or under protest. Slight enlargement of the spleen may occasionally be detected, but is more frequently not observed. More severe cases, beginning more or less abruptly, develop primarily the symptoms of remittent fever, and diagnostic doubts only arise when the absolute resistance to anti-periodic treatment and the gradual appearance of typhoid symptoms excite suspicions of the incorrectness of the original diagnosis. These latter are the cases that, now correctly, again incorrectly, suggesting the combined influence of two specific morbific poisons, are dubbed, by most practitioners in malarious districts, "typho-malarial fever."

From my note-books I have selected the following cases as fairly representing the mild forms of typhoid fever to which my paper has reference.

Case I.—A girl, nine years old, residing for the summer in Baltimore County, among the hills overlooking Lake Roland, one of the water storage lakes of the city, was taken sick July 22, 1884. The attack began with languor and headache, anorexia, and nausea. She had no chill, but remained languid and thoroughly uncomfortable. She was not confined to her bed until the 27th, when it became evident to her mother that she was unfit to be about. I saw her at midday of the 28th. Her temperature was then 100.6° F. At 9 P.M. it was 102.6° F. She was nauseated, and vomited several times. During the day she had several loose stools, and suffered intensely from headache. She was much debilitated. Some pain was referred to the epigastrium, but there was no belly-tenderness to pressure. The tongue was coated with thin white fur. The countenance was distressed. As soon as the nausea was overcome by appropriate measures, a milk diet was instituted, and fifteen grains of quinine sulphate in pills were given in three doses daily. Diarrhœa was controlled at once, and was not again present during her illness. The pulse, temperature, and, for a time, the respiration, were systematically observed, three temperature observations being taken daily (at 7 A.M., and at 3 and 9 P.M.) as shown in Chart I. Cinchonism was quickly induced, and maintained for several days, when the powerlessness of quinine to control the fever was demonstrated, and the dose was diminished to six grains daily. This was continued until convalescence was established, and was the only medication employed.

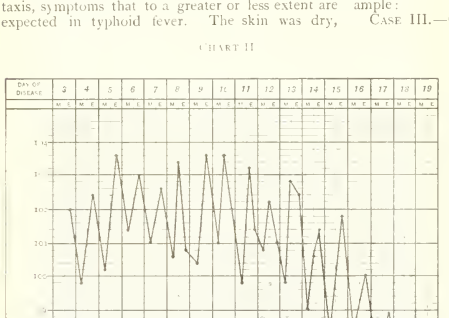
slight behavior throughout, the continued fever was the only prominent symptom. A most instructive feature of the case was the morning apyrexia, dating from the nineteenth day. This temperature variation at once suggests what writers have described as the transition of a remittent fever to an intermittent. With the hope of preventing this evening exacerbation, quinine was again pushed to pronounced cinchonism, but in vain. Morning apyrexia, however, is a common phenomenon of the latter period of typhoid fever, and a disregard of this fact is answerable for many of the so-called relapses of this disease, especially in private practice, where the medical attendant unwisely judges of the condition of his patient from a single morning daily visit.

Case II.—On August 6th the six-year old sister and room-mate of my first patient was observed to have fever. She had been somewhat listless for two days previously, and had been warm, and without appetite. The evening temperature on August 8th was 102 Fahr. Systematic observations were begun on the 9th. Chart II. shows the temperature observations, and bears out the remittent-like character of the attack as shown by the symptoms. Not to prolong unduly the history of this case, it will suffice to say that, although the fever was pronounced, there was at no time hebetude, delirium, diarrhœa, abdominal or iliac tenderness, roseola, tympanites, splenic enlargement, bronchitis or epistaxis, symptoms that to a greater or less extent are expected in typhoid fever. The skin was dry,

CHART II



the conjunctivæ somewhat injected, the tongue moist and slightly coated. The child was thirsty, and was always eager to drink its apportioned share of milk at the stated intervals. She slept well at night, and during the day was bright and playful, indeed, disposed to romp. Sulphate of quinine was given in daily doses of twelve grains, divided into three doses, until intense cinchonism was induced. This effect was kept up until the fifth day, when its powerlessness to control the fever having been demonstrated, the daily dose was reduced to six grains, and was continued until defervescence, which occurred on the seventeenth day. Upon the establishment of convalescence both children were considerably wasted.

No other member of the household was attacked. The sanitary condition of the house gave no explanation of the origin of the attacks. The drinking water was pumped from a spring remote from any contaminating influence. The ice-house, however, had been filled from a pond used as a power for pumping the spring water to the house; and this pond received not only the overflow-water of the cesspool of the house, but of that of one or two others on the neighboring hillsides. Upon discovering the source of the ice supply, its use was at once discontinued. During the previous season one or two cases of "slow fever" had occurred in the vicinity.

It would be difficult to regard my second case as other than one of remittent fever, were it not for its defiance of anti-malarial treatment and the concurrence of the first case, which was sufficiently distinctive of typhoid fever.

Typhoid fever in children, however, is more often atypical than not, the most characteristic symptoms often failing. The resemblance to remittent fever is almost as frequently observed in adults, in the milder forms. The following case affords an example:

Case III.—G., about twenty-three years old, a clerk, unmarried, tall and slender, leading an active life, spending the summer months in the country in a small house, near which there was an open ditch which retained water for several days after rain storms. In previous years he had had a number of attacks of malarial fever, which is occasionally observed in the neighborhood. On August 28th, after having felt unusually well for some time, he had a chill. Continuing to feel badly, he called to see me at my office on the succeeding day. He had headache, pain in the back, and general discomfort, but retained some appetite; his face was flushed, and his tongue coated; his bowels had been moved the day previous; there was no abdominal tenderness; his temperature at 3 o'clock P.M. was 102.6° Fahr. He was told to go to bed, which he did at the house of a relative in town, and took until ten o'clock the following morning forty-two grains of sulphate of quinine. Cinchonism was not very pronounced, however; a milk diet was instituted; the daily dose of quinine was fixed at twenty-four grains. The course of the disorder is shown in Chart III.

September 1. The bowels not having been moved since the 27th, two seidlitz powders were given, one in two hours after the other; a slight action was had toward morning; the tongue was coated with a thin,

whitish fur; during the night he vomited, and had slight epistaxis; there was some pain in the back;

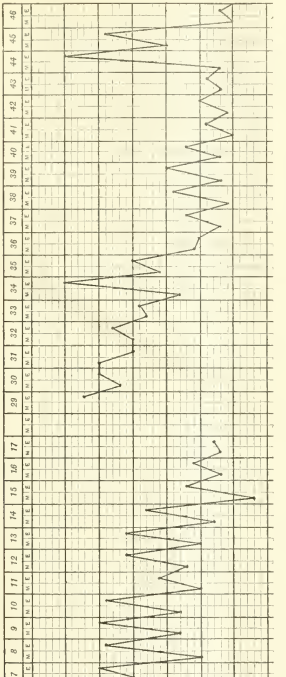


Chart III.

there were no rose-spots; no abdominal tenderness; the expression was bright and the mind active; there was no headache; the patient read in bed, and betrayed interest in his case and in current topics.

2d. Bowels moved twice during the night (from aperient). From this date the course was quite uniform. The tongue remained slightly coated, but moist; constipation was obstinate, and only relieved by saline purgatives; no roseola; no iliac tenderness nor gurgling were observed; the urine contained no albumen; hebetude or nervous symptoms did not develop; he slept well, and during the day was comfortable, reading diligently; his appetite was good, but only milk and beef-tea were allowed; there was, perhaps, some enlargement of the splenic area of dulness.

Complete defervescence took place on September 13th, or the seventeenth day of the fever. Convalescence seemed established. Without permission he spent the 21st at a relative's, but felt cold and miserable. On the 22d, of his own accord, he took ten grains of blue mass and two seidlitz powders, and the following morning a dose of Hunyadi water. This was followed by violent nausea and vomiting, but by a single stool. His temperature was now 103° F. He was ordered to take twenty-four grains of quinine daily. This was continued until October 2d, when the daily dose was reduced to twelve grains. On September 26th, his bowels not having been moved for several days, he took solution of the citrate of magnesia, two liquid stools resulting. Tongue coated with thin white fur. Belly not at all tense, but two roseola-like spots were detected. There was no belly-tenderness. The temperature slowly declined, and became normal on October 7th. With a slight interval of vesical tenesmus with a sudden rise of temperature, recovery was uninterrupted though tardy.

Ten days previous to G.'s illness, his younger brother, who had been living with him, had fallen sick, and had been attended in the country by Dr. R. W. Erickson, of Elkridge Landing, Howard County. He had a typical and severe attack of typhoid fever, and had a protracted convalescence. It proved impossible to ascertain the source of infection of these young men.

My note-books contain a number of similar cases, and my clinical experience has included a large number; indeed, not a year passes that they are not brought to my notice, both in my own practice and in that of medical acquaintances.

There are few diseases that are more distinctly marked by characteristic features than typhoid fever, and although one or more signs are absent in many cases of moderate severity, enough may be identified to make an easily recognizable picture. So inconstant are the separate typical symptoms, however, that Liebermeister has confessed that in typhoid fever we have not a single pathognomonic sign. While this inconstancy is generally recognized, there is not a general realization of the mildness with which the disorder very frequently pursues its course. "Walking typhoid," the *typhus ambulatorius* of the Germans, though usually considered a rare form, is in fact a very common one. The cases which declare themselves by the sudden development of alarming or fatal symptoms probably form but a small proportion of the whole number.

We have had to modify many of our views con-

cerning this disease. Though no less an authority than Wunderlich[1] declared that a disease in a child or adult under middle age, in which, between the fourth and sixth days, the evening temperature does not reach 40.5° C. (103.1 F.), is not typhoid, we now know that he is far from speaking correctly, even for severe forms of the disease. Strabe noted fourteen cases during the whole course of which a normal, at times a subnormal, temperature was observed. In these cases the accompanying symptoms established the diagnosis beyond a doubt.[2] Fräntzel, in more than one hundred cases of severe typhoid fever, treated in the field-hospital during the late Franco-Prussian war, observed forty-one cases in whom the temperature did not reach 39 C. 102.2 F.[3] In three of these it never attained 37.3 C. 99.14 F.[4] These were all severe cases. Strabe's mortality was 14.1 per cent., that of Fräntzel 39 per cent. for the forty-one cases.

In mild forms of the fever the frequent occurrence of but slightly elevated temperature is not at all uncommon, and is widely admitted. Liebermeister noted, at Basle, affections which ran their courses without fever, and yet could, with good reason, be referred to typhoid infection. Lommis, in linking the "mild type" of cases of typhoid fever with the "walking type," states that the eruption appears in them early, and is scanty and brief, and that diarrhœa is present in most cases. This description undoubtedly suits many of our cases in Baltimore as elsewhere, but there is a large class, certainly typhoid in character, in which constipation is the rule, and rose-spots are decidedly exceptional. Indeed, these two symptoms are much less constant in well-defined though mild typhoid fever than many of our writers would lead us to conclude. Liebermeister, in one hundred patients in whom the fever never exceeded 104° F., and in many 102.5° F., and in whom the course was markedly shortened, observed roseola in but twenty-one, diarrhœa in forty-one, while splenic enlargement was observed in seventy-one.[4] He has also reported from his hospital service many cases entered as febrile and afebrile abdominal catarrh, which he attributes to typhoid infection. A number of writers have made similar observations.

In two admirable papers, one entitled "On the Diagnosis of Mild Cases of Typhoid Fever," etc.,[5] the other "On the Mild Forms of Continued Fever," etc.,[6] Dr. W. W. Johnston, of Washington, has described these forms of typhoid fever with so much faithfulness and skill that I should hesitate to present my own views upon what may by many be considered as already demonstrated, were it not that many observers, in malarial districts especially, persist in regarding them examples of "typho-malarial" and "remittent malarial fever." Malaria often complicates typhoid fever, but it oftener happens that its presence is assumed unjustifiably. The mental bias is often so strongly pronounced in favor of malaria, that even the strongest evidence fails to prevail against it.

Remittent malarial fever is so simulated by the cases under discussion that the diagnosis must wait upon the crucial test of treatment. It is true, that all writers admit that occasionally antiperiodic remedies, generally efficient, fail to control the malarial paroxysm. This occurs especially in many cases of pernicious fever, and in certain adynamic remittents where profound systemic disturbance is apparent; but in the milder forms of remittent fever that correspond to the milder form of typhoid fever, the behavior of the individual under quinine practically settles the question. If the full influence of the anti-periodic has been exerted for four or five days, or a week, without the desired result, the diagnosis of typhoid fever becomes justifiable, and the prognosis may be made with a high degree of confidence.

Not often earlier than the end of the second or later than the fourth or fifth week the fever will terminate by gradual lysis, rarely by crisis. This will be the almost constant result. I have never seen a patient die in whom the disease took the course indicated, and who was submitted to proper control. There are exceptions to the rule, however. Dr. Johnston has given a most interesting history of a case of very mild typhoid fever, of the atypical character to which I refer, suddenly developing fatal complications.

The occasional occurrence of death in cases of "walking typhoid" also shows that even the mildest cases are not without danger. These cases, however, have the disadvantage that they often elude observation and incur too often the dangers of complications from a persistence of those influences that tend to precipitate them. Yet, unquestionably, very many of the cases of "walking typhoid" never develop alarming symptoms, and are never recognized, the patient probably never interrupting his daily work. Doubtless many, in mild degree, display, upon examination, the more characteristic signs of typhoid fever, diarrhœa, rose-spots, enlarged spleen, etc., but it is quite certain that in not a small number these signs fail to be discovered. They are also absent in a large proportion of those cases of typhoid fever which have been the subject of this paper, and, in consequence of their absence, the true nature of the disease is often unrecognized, and the pathological responsibility thrown upon "febricula," "simple continued fever," "gastric fever," "bilious remittent fever," "remittent malarial fever," etc. From beginning to end they lack the most characteristic symptoms of typhoid fever, and should be diagnosticated from the persistence of fever, its defiance of specific treatment, and the occasional demonstration of their dependence upon the typhoid principle.

For the future it is quite safe to predict that a solution of diagostic difficulties will be attained often through the rapidly increasing knowledge derived from bacteriological research and culture observations.

FLOATING SPLEEN: SPLENECTOMY; RECOVERY.[1]

By JAMES McCANN, M.D.,
PROFESSOR OF SURGERY, ETC., IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

Reported by J. W. LEONARD, M.D.,
LATE HOUSE SURGEON, WESTERN PENNSYLVANIA HOSPITAL, PITTSBURG, PA.

So scant and unsatisfactory is the literature bearing upon splenectomy that we trust the following detailed history may not be devoid of interest.

Mrs. C. A. G., aged twenty-nine, born in America, housewife, was admitted to the hospital May 6, 1886. She stated that she had suffered during the past six years from an abdominal tumor, associated at irregular intervals, with severe hemorrhages.

Her family history was good, there being no hereditary dyscrasia; her parents aged about seventy-one years; brothers and sisters are all living, except one sister, who died of some "obscure nervous affection."

Previous to the present trouble, the patient enjoyed perfect health; though living in a malarious district, she never had ague; has menstruated since thirteen years of age, and was always regular till one year ago when, after an attack of hematemesis, her "periods ceased for a few months," nor had she menstruated since March, 1886, the time of the last hemorrhage. She has been married seven years; has no children, but had three abortions in 1880, '82, and '85, at the fifth, eighth, and second month respectively.

Each of the mishaps was apparently causeless, and without warning, except the last, which may have been induced by large doses of ergot administered for the relief of hemorrhage. But, be this as it may, after the first abortion she suffered more or less constantly with vertigo and general nervousness; the tumor, though probably having existed for a long time, was not noticed until the morning following the second miscarriage, in 1882, and the first attack of vomiting of blood occurred two months previously, and was followed after the lapse of ten days by another; a third occurred about six months later, a fourth in July, 1883; a fifth in September, 1884; a sixth in July, 1885; a seventh in December, 1885, and an eighth in March, 1886.

The blood was always vomited except in one instance, when part passed by the mouth, and part per rectum; on another occasion the greater portion escaped by the latter course. The attacks were marked by suddenness of onset, and most alarming severity, the only premonitory symptom being a day or two of drowsiness and general malaise; then, the patient usually waking from sleep, more quiet and profound than had been her custom in health, would complain of salty taste and intense nausea. Scarcely would she experience these sensations, until the blood came gushing from mouth and nostrils, never ceasing till syncope, nature's hemostatic, would check the flow, and leave the victim all but exhausted.

The period following such an ordeal was generally characterized by good health; appetite, lost weight and strength were soon regained, but only preparatory to another siege. The intervals became shorter, and each hemorrhage more severe than the preceding, until with the last, the unfortunate woman lay pulseless, and apparently dying.

She then entered the hospital—a perfect picture of anæmia; her skin was pale and waxy; lips and conjunctivæ almost colorless, body emaciated; hands and feet cold; respiration shallow; temperature subnormal; pulse rapid, feeble, and compressible. She was restless, and complained of alternate flushes of heat and shivering sensations, of drowsiness, vertigo, tinnitus aurium, and dimness of vision. Physical examination of the abdomen revealed a tumor occupying the left iliac, and extending to the suprapubic region. Its surface was flat and smooth, contour well-defined, of oblong or roundish shape; dimensions four by five inches; consistency more than semi-solid; percussion note dull, and the auscultatory signs were negative. It was extremely mobile, though preferring the left iliac region, the mass could be shifted, either by change in the position of the patient's body, or by the surgeon's hand, into any part of the abdominal cavity, even above the umbilicus.

The patient stated that, for a short time after its appearance, the swelling increased rapidly in size, but that within a year or more its condition had been in this respect stationary, except just before a hemorrhage, when it would become considerably enlarged; that it would pulsate violently during an attack, at the same time diminishing in size, but during the interval its former dimensions were soon regained, there being then absolutely no evidence of pulsation. Another conspicuous feature of the case was the absence of pain throughout the history of her illness, with the exception of such discomfort as might be referred to chronic constipation and occasional attacks of vesical tenesmus.

Vaginal examination showed that the tumor extended deeply into the cavity of the pelvis, occupying especially its left half, from which position it could be readily dislodged by the index finger, after the manner of ballottement. The uterus was of normal size, but slightly displaced to the right side. The sound, as well as conjoined manipulation, proved that either the uterus or the tumor was movable, the one without the other. There was no evidence of kidney, liver, or other glandular disease; the lungs and the heart were also normal, though in case of the latter, a well-marked hæmic murmur could be heard at the base. Percussion over the splenic area, from the ninth to the eleventh rib under the axilla, elicited abnormal resonance.

After careful consultation, surgical interference was deemed the only means of relieving the patient of further suffering; but such was the state of debility that this step would not have been justifiable without previous improvement in her general health. She was, therefore, placed upon tonic doses of quinia, with tinct. ferri chloridi, and acidum phosphoricum dilutum, and after three weeks had gained sufficient strength to warrant the removal of the tumor. Accordingly, a brisk cathartic was ordered

[1] Read at the meeting of the American Surgical Association, Washington, D. C., 1887.

on the night preceding the operation, and on May 27, 1886, the bowels being further relieved by a copious enema of soap and water—the patient having fasted, received the anæsthetic (pure ether), and laparotomy was performed by an incision five inches long, and in the median line, its upper extremity terminating one inch below the umbilicus. The lips of the wound were then held aside by means of retractors, and the upper part of the tumor brought plainly into view: the lower half dipped deeply into the pelvic cavity, and was concealed by a broad and vascular fold of omentum; on lifting the mass (now recognized to be the spleen), another portion of omentum, traversed by more than a dozen very large and tortuous veins, was found to have become firmly and extensively adherent to its posterior and external surface.

Though manipulated with the most delicate care, these adhesions gave way, necessitating the application of clamp forceps to arrest hemorrhage. The capsule of the spleen also yielded, tearing rather widely at a point close to the hilum: a very profuse gush of blood followed, but was promptly controlled by an assistant who made pressure by grasping the ruptured portion in his hand.

The pedicle, consisting of the splenic vessels, etc., was then transfixed and secured by a double carbolized silk ligature, another ligature being applied as an additional safeguard against secondary hemorrhage. After the vessels of the omentum had been treated likewise, all the ligatures being cut short and dropped into the cavity of the abdomen, the latter was thoroughly cleansed, and the splenectomy completed (1.15 P.M.) by closing the wound with deep, interrupted silver sutures, including the peritoneum.

The operation was done under Listerian precautions, under the carbolic spray; the line of incision dressed with dry iodoform, protected with antiseptic gauze, secured by adhesive plaster, and all covered by a heavy layer of absorbent cotton, held in place by an abdominal (flannel) bandage. Not more than two ounces of blood were lost, and yet the patient suffered the most profound shock, requiring, both during and after the operation, the free administration of whiskey and ether, hypodermatically, to stimulate and sustain her extremely feeble circulation, but she soon reacted, and at 6 P.M. had a pulse of 100, a temperature of 99.5°, and normal respiration. She stated that she felt comfortable, though weak and stupid.

For a short time she appeared to lose flesh, and to become more anæmic; there was slight increase in the number of white blood corpuscles, but no perceptible enlargement of the liver, thyroid, or lymphatic glands as formerly observed in similar conditions by Zesas, Tauber, and others. Under the carefully directed after-treatment, which was principally dietetic—consisting of milk, beef-tea, rice, eggs, etc., at short but regular intervals—she soon began to improve. On the second day after the operation a large quantity of gas escaped from the stomach and intestines, and, on June 1st, her bowels moved freely. The wound was also examined: its edges had already firmly united, and there was no evidence of suppuration. The stitches, eight in number, were then removed, and fresh dressings applied.

The case progressed favorably, her pulse ranging from 88 to 100, and her temperature never rising above 100⅘° until the eleventh day, when catheterization became painful, the patient complaining also of slight tenderness on pressure in the left iliac region. This marked the onset of a somewhat alarming and rather obstinate attack of phlegmasia alba dolens. During the ensuing week the intensity of the symptoms increased, the tenderness and œdema spreading to the left loin, vulva, buttocks, and lower extremity, along the entire course of the left femoral and internal saphenous veins to the left foot. She suffered, also, from profuse watery diarrhœa and loss of sleep, there being at the same time marked increase in the febrile excitement. But this complication slowly yielded to an anodyne, astringent and tonic plan of treatment, so that by June 18th her pulse and temperature were normal, and the patient was free from all distress. She was discharged from the hospital June 29, 1886—thirty-three days after the operation. Her health continued to improve; she menstruated in September and in October, 1886, but soon after that occurrence became *enciente*, and is now in the eighth month of her pregnancy.[1]

The symptoms and complications attending this woman's condition are now readily explained. The hemorrhages were probably due to certain pathological changes in the vessel-walls, induced by the damming back of blood from the misplaced spleen into the other abdominal viscera—bleeding occurring whenever the intravascular pressure would become sufficiently great to rupture the vessels. The intimate connection of the splenic circulation with that of the stomach and intestines, as well as the functional activity of the latter, are sufficient to explain the seat of the accident.

The abortions were caused by the irregular blood supply; the general hemorrhagic tendency, the malposition and reflex irritation of the pregnant womb.

The constipation, the displacement of the uterus and the vesical tenesmus were due, in great measure, to pressure exerted by the tumor. The spleen was "floating," probably, from some congenital defect in its attachment, there having been no history of effusion into the thoracic cavity, of corset-constriction, nor of other injury to the chest-wall.

The fact that phlebitis followed the operation may be accounted for by the hyperinotic state of the blood—a condition common to all such cases—and favoring coagulation at some convenient point in the course of the circulation. In this instance, the point of least resistance seems to have been the common iliac vein—the left rather than the right, because it is more tortuous and joins the vena cava at a more oblique angle than does its fellow of the opposite side. Again, the walls of this vessel, not only diseased, but also impaired by the combined pressure of the spleen and the rectum, were

[1] Since the above writing, the patient was confined at term, but the child was born dead.

further damaged by removal of the support afforded by the tumor.

The profuse diarrhœa must have resulted from the congestion of the intestine, which was increased by the removal of the spleen, together with that peculiar state of the vascular tunics and of the blood, which favors the escape of its serum.

As to the pathology of the splenic tumor, there was nothing especially interesting, except that this was not an instance of *supplementary* spleen, such as have been not infrequently observed post-mortem. It weighed, after the escape of a considerable quantity of blood, fourteen ounces; was of little more than normal density; its dimensions, five by five and a

Recorded Cases of Splenectomy.

The operation in all these cases was by incision of the abdomen in the median line.

half inches; border slightly rounded; was very vascular, friable on section, but paler than usual, its color and consistence resembling, on the whole, a greatly enlarged kidney. Microscopic examination detected nothing abnormal, save slight thickening of the trabecular and intercellular connective tissue.

The patient's blood contained more white corpuscles than normal, but not enough to constitute leucocythæmia.

With regard to the functional effects of removal of the spleen, we are disposed to confirm the opinion of Crede, who observes (*Medical Record*, July 29, 1882): First, that the spleen can be extirpated without injury to health, except a *temporary* anæmia. Second, that its extirpation produces a marked temporary anæmia, with increase of white corpuscles, as well as decrease of red.

Tauber further states (*Journal American Med. Association*, July 12, 1884): First, that the spleen is one of the main reservoirs of the blood, whose influence on the circulation is seen—after its removal—in the congestion of the liver, kidneys, and especially lymphatic glands (not perceptible in the case now under consideration, though probably present). Second, that no physiological affinity exists between the thyroid and the spleen. Third, that the removal of the spleen does not impair the digestive functions or nutrition.

In addition to these facts, we observe that conception and parturition are possible after splenectomy; also, that the spleen, alone, is not the "cradle and the grave of the red blood-corpuscle."

At the present writing, more than a year after the operation, the woman's health is good, and she is able to perform without discomfort all the duties incumbent upon a farmer's wife, the only remaining trouble being slight swelling and weakness of the left lower extremity.

In conclusion, we append a review of the history of excision of the spleen, also certain interesting statistics compiled by Prof. James McCann.

Splenectomy, for all causes, has now been performed fifty-one times, with a mortality of 62.8 per cent. In addition to these *complete* excisions, the table given by Otis (*Med. and Surg. History of the War*, Part 2, vol. ii. pp. 152–153) shows *partial* excision to have been performed in twelve cases, for various injuries of the organ. All these cases recovered.

By reference to this table, and to that of Mr. Herbert Collier (*Lancet*, February 11, 1882), it will be seen that the operation of *complete* excision of the spleen for injury, as well as for dislocated or "wandering" spleen, and for hypertrophy uncomplicated with leukæmia, afforded a very gratifying degree of success—thirteen operations with eight recoveries. On the other hand, the same tables show a ghastly record for the cases in which the operation was performed for hypertrophy of the spleen associated with leukæmia—sixteen cases in all, without a single recovery.

The results obtained since Mr. Collier's publication show a steady and very gratifying improvement in the percentage of recoveries. The table appended to this paper includes all the cases operated upon since 1881, so far as I have been able to find any record—seventeen complete excisions, with twelve recoveries. Included among the successful cases are two, those of Franzolini and Alesio Giovanni, in which the splenic disease was probably complicated by leukæmia. It is possible, however, that not all of the fatal cases have been reported. Thus, Tait refers (*Ovarian Diseases*, etc.) to two instances within his knowledge in which hypertrophied spleen was mistaken for ovarian tumor, and the operation for the removal of these supposed cysts terminated fatally in both cases, no report of the mistake ever being published. The chief source of danger in the operation consists in the marked tendency to hemorrhage—a tendency unfortunately present in all cases of splenic disease—and the mortality, in a large majority of the fatal cases, has been due either to uncontrollable bleeding during the operation—as in one of Bryant's cases, death having occurred in fifteen minutes from the loss of blood; or to secondary hemorrhage at the seat of ligature, or to capillary oozing from the highly congested abdominal viscera—as in Terrier's patient, where death followed from capillary hemorrhage into the peritoneal cavity, twenty hours after the operation.

In the discussion which followed the report of Crede's case to the German Surgical Society (*Centralblatt f. Chir.*, 1882, No. 29) six other cases were mentioned by different operators, with but one recovery. However this may be, the success attending the recent excisions is so very encouraging that we may hope that even in cases of hypertrophy complicated by leukæmia, splenectomy will not always merit the condemnation which it receives at present, and not always be regarded as "physiologically unsound and surgically unsafe," as Mr. Bryant characterizes it, nor as the "useless and deadly experiment" which Mr. Collier considers it to be.

COLOR BLINDNESS AMONG RAILROAD EMPLOYÉS.

By WILLIAM THOMSON, M.D.,
PROFESSOR OF OPHTHALMOLOGY IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

THE conflict between the officers and the employés of the Reading Railroad, which has occupied recently the attention of the public, and has threatened to produce a suspension of work on that road, has reopened the question of color blindness among railroad employés, and led to a full demonstration of its existence among the employés engaged even as enginemen, where the defect might lead to serious accidents, with loss of property and life. The officers of the road have selected the system for examination suggested by the writer, and employed to a full success for more than five years past on the Pennsylvania Railroad, and have appointed me to supervise its details, and, as ophthalmological expert, to decide all doubtful cases after careful examination of those found defective by the non-professional examiners of the company.

The conflict is nearly over, since demonstrations of the optical defect in engineers, made before a committee appointed by the employés have satisfied them

of the propriety of the testing, and the safety of the travelling public demands the removal of all color-blind persons from positions where their optical defect might be the cause of distressing accidents. In the recent demonstration I was able at my office to show that an engineman declared a red danger signal, made by placing red glass in front of a large gas light at a distance of two feet away, to be a green light; he was also not only unable to distinguish a red from a green flag within six feet, but he failed to classify the flags, white, red, green, and blue, properly, even when allowed to take them in his own hands.

The system adopted by the Reading Railroad is the one in use on the Pennsylvania Railroad, and owes its value to the fact that large bodies of employés can be brought under inspection, and their defects discovered by non-professional examiners. It has been fully described in The Medical News of January 14, 1882, in the second edition of Nettleship's work on *Diseases of the Eye*, and in a paper read before the American Association for Advancement of Science, in September, 1884, and in the *Popular Science Monthly* for February, 1885, and to those sources the reader is referred for further information.

Previous to its adoption by the officers and directors of the Pennsylvania Railroad two thousand men were examined, and their blanks submitted to me, and the color-blind men sent to my office for final action. Mr. Pugh, General Manager, stated in September, 1884, that there were thus detected four per cent. of men color blind, and ten per cent. of men deficient in acuteness of vision, and that, although it was very difficult to keep accurate notes of all examinations, he was satisfied that all dangerous persons had been removed up to that date, when over twelve thousand employés had been submitted to the system.

The statistics obtained upon the two thousand men were used as the standard by all the Division Superintendents, and however difficult it might be to report to the central office the full details of their examinations, they were always controlled by these known and accepted ratios. It has not been found requisite to send all men deficient to the ophthalmological expert, since they did not demand it, but submitted to the changes rendered necessary without opposition, hence I am unable to furnish exact reports of the examinations made at remote portions of the road. Most of the color-blind men have passed under my hands, as well as many cases of astigmatism, optical defects, and diseases or injuries reducing the sight below the standard, and the results may some time be found worthy of publication.

An opportunity to present the last opinions of the officers of the Pennsylvania Railroad has been afforded by a request which was made by the German Government, through its Minister, to the Surgeon-General of the United States Army for statistical and other information on the subject, and this letter, referred to me by the Surgeon General, has been answered by Mr. Pugh, who has kindly made efforts to obtain the figures from the great organization of which he is General Manager. He writes, under date of July 7, 1887, and says:

"I regret that so long a time has elapsed since the receipt of yours of May 25th and this reply. The delay has been occasioned by our efforts to obtain some statistical information, which I regret to find has not been kept up as closely as was intended. I enclose herewith statements showing the number of employés examined during the past five years, with the results stated.

"I can only add that we have attained the most satisfactory results from the system, and I think we can confidently claim that sense of security which follows the belief that we have no one employed in any position in which the use of signals is required, whose color-sense and sense of vision will not enable him to accurately determine all signals by which his action is governed."

Total number examined on lines east of Erie	25,158
Color blind	481
Defective vision	661
Hearing	158

I am informed that the system has been found so satisfactory that it has been extended to the lines west of Pittsburg, and no doubt is now in use throughout all the lines controlled by the Pennsylvania Railroad.

It will be remembered that this system is also used to prevent the admission of defective men into the service, and that the apparently small percentage of color blind in this table may be ascribed to the non-application of men who know their deficiency, and to the fact that men in the service knowing their defect would leave the road before examination, and thus escape detection, and be enabled to gain employment on other roads, where no examinations are required. Perhaps twelve or thirteen thousand was the number who were subject to examination by virtue of being in positions where color signals were used to direct them, in 1884, and the difference between that number and the total 25,000, would be made up of new men who would present a small ratio of those below the standard, since men conscious of color blindness, or poor sight, would not apply.

The fact that the intelligent officers of the Pennsylvania Railroad have adopted this system, purged their old force of all dangerous men, extended its use to all parts of their immense railroad, and now oppose it as a barrier to the admission of men thus unfit for service, is the best evidence that can be adduced to claim for it a successful place among the efforts to render scientific truths of practical value to the world. It is hoped that the Reading Railroad will be sustained in its contest with its employés by the example so quietly conducted by the Pennsylvania, and that the reform so necessary for the travelling public and for those employés who carry their lives in their hands daily, may be conducted to a happy finish.

MEDICAL PROGRESS.

Sunstroke and its Prevention.—The *Lancet* of July 30, 1887, gives the following advice, which is most opportune in the present heated term:

Several cases of sunstroke have recently been re-

ported from the west of England, and intelligence from America shows that deaths from this cause have also been remarkably frequent there. A few observations on this subject should, therefore, be not unseasonable at the present time. To speak of sunstroke as being due to more causes than one may sound at first sight rather like a contradiction in terms, but there can be no doubt that besides the principal influence at work in such cases there are others of real though secondary significance. In seeking to explain the causation of this morbid state we must, indeed, regard at least two different conditions as commonly acting together to produce the result. One of these is external heat, not necessarily that of the direct solar rays; the other is the presence in excess of impurities in the blood circulation, with a want of due nutrition in the tissues which it supplies. The consequence of this abnormal state of body is necessarily to delay the blood current, and the state of congestion thus engendered in the nerve centres of the brain and cord renders the latter unusually irritable to the action of external stimuli, of which external heat is, for the case we are discussing, the most important. It follows accordingly that prevention must include some care as to modes of living, as well as means of regulating or resisting heat from without the body. For example, the free use of alcoholic stimulants, which tends to impair nutrition, is no longer considered to be advisable; while tea and coffee, which check the formation of waste products, are proportionately valuable. Tight clothing about the chest is generally condemned as being likely to impede the aëration of blood in the lungs, and experience has proved that for a similar reason the imperfect ventilation of workrooms in warm summer weather is conducive to heatstroke. As regards protection against the sun's rays, it should be remembered that not only the head but the back of the neck must be suitably guarded in order to insure the traveller against the risk of injury. The wearing a damp handkerchief, or a leaf, such as that of the cabbage, next the head has also been found very useful. One word as to the immediate treatment of a case of sunstroke. In some instances, doubtless, not even the readiest assistance will save life, but in a case of need it is well that all should bear in mind that the most effectual form in which first aid can be rendered is the application of cold—as cold water, ice, etc.—to the head and neck.

FORMULÆ FOR ACID CALCIUM PHOSPHATE SOLUTIONS FOR THE TREATMENT OF TUBERCULOSIS.—FREUND, of Vienna, publishes the following, as used by KOLISCHER (THE MEDICAL NEWS of June 25, 1887, p. 710). For hypodermatic injections:

Calci. phosphorici neutral. . .	5 parts.
Aquæ destill.	50 parts.

Add phosphoric acid until a perfect solution results; filter; add

Acid. phosphor. dil. . . .	$\frac{1}{10}$ part.
Aq. destillat. . . .	q. s. ad 100 parts.

For an escharotic effect upon tuberculous ulcers and indolent granulations, the following is used:

Calci. phosphorici neutral. . .	50 parts.
Aq. destillat.	500 parts.

Add phosphoric acid until a perfect solution is obtained; filter; add

Acid. phosphor. dil. . . .	60 parts.
Aq. destillat. . . .	q. s. ad 1000 parts.

Gauze may be soaked in this fluid, and used in dressing tuberculous fistulæ and pockets.—*Wiener medizinische Presse*, No. 24, 1887.

COCAINE IN HAY FEVER.—DR. BISHOPS, of Chicago, in the First Prize Essay of the United States Hay Fever Association for 1887, writes as follows on this subject:

Cocaine, in a four or ten per cent. solution, applied with a camels' hair brush, gives speedy relief. The patient should never omit clearing the membrane of mucus before applying any local remedy, else the medicine is diluted and prevented from acting on the seat of irritation. Better than the solution is a six or ten per cent. powder of cocaine and sugar of milk, applied to the nasal cavity with a pocket insufflator or powder-blower, small enough to carry in the vest pocket and to be used unnoticed the instant an attack threatens. The vulcanite tip of the soft rubber tube should be applied to the lips, when a gentle puff of the breath will blow a cloud of the anæsthetic powder into the nasal cavity, when the hard rubber tube is properly directed. This instrument is constructed after my large office insufflator, which is operated by a rubber bulb containing soft-rubber valves. The effects of cocaine may last several hours, but repeated applications may be necessary to keep up continuous insensibility of the membrane during prolonged attacks. However, it should be known that some persons possess an idiosyncrasy which forbids the use of cocaine. The primary action may produce anæsthesia and anæmia of the membrane, regularly, but the bloodvessels may become dilated and remain so, instead of returning to their normal calibre as they do in most cases. This condition of secondary hyperæmia is attended with intense hyperæsthesia and all the symptoms of severe hay-fever. Fortunately there seem to be few who are so distressed by this remedy, and I have employed it in many cases of various diseases without observing any disagreeable symptoms.—*Journal American Med. Association*, July 23, 1887.

THE TREATMENT OF DIARRHŒA BY CANNABIS INDICA.—DRS. BOND AND EDWARDS give the following prescription in the *Practitioner* for July, 1887, which they have found very useful:

℞.—Tincturæ cannabis indicæ .	♏x.
Liquoris morphinæ . .	♏v vel ♏x.
Spiritus ammoniæ aromatici	♏xx.
Spiritus chloroformi . .	♏xx.
Aquam	ad ℥j.

To be repeated every one, two, or three hours, according to circumstances. Directions: *No food for several hours, but a little brandy and water.* We have not seen one case run on to a fatal issue under this treatment.

THE DANGERS OF HYPNOTISM.—LARROQUE expressed the following views before the Paris Medico-Psychological Society at a recent meeting: In Paris, as in other places, hysterical patients are put asleep and

suggestions made to them, but many times without effect, and sometimes unfortunate results have occurred. I cite amongst others, the case of a young girl subject to slight vomiting. The doctor, knowing that he had to do with an hysterical patient, made use of hypnotism, in which he was well versed. On awakening, the girl had a contracture of the foot, which remained for some months. Neither putting her to sleep nor suggestions could make this contracture disappear. Afterward it was followed by difficulty in walking, by atrophy of certain muscles, by the retraction of the tendo Achilles, and perhaps by an adhesion of the joints. This contracture ought not to surprise us when we think of the neuro-muscular hyperexcitability in certain phases of hypnotic sleep, especially in the lethargic state, when the lightest touch or breath may produce a contracture which ought to be instantly undone. Here we have a young girl the victim of hypnotism; such cases are numerous.

It does not stop there. It is averred that, in causing hysterical patients to sleep, their mental derangement is confirmed. By hypnotism we can bring on mental disturbance of which the last term is that of hysterical insanity. Moreover, if these patients are often put to sleep, they can in the end fall asleep of themselves; consequently these intellectual troubles can only be accentuated. These grievous phenomena may appear, not only after repeated experiments, but even after one trial. For example, let us take the case communicated to me by Dr. Deligny. A young girl after the first hypnotic séance remained during three weeks in a state of complete stupor. I have said enough to prove the dangers of these experiments, which are not always attempted for a praiseworthy aim.—*Annales Medico-Psychologiques*, May, 1887.

Corrosive Sublimate in the Treatment of Diphtheria.—Stumpf has used the following prescription with excellent results:

℞.—Sublimat. . . . . gr. 3.
Aq. destil. . . . . ʒ 5¼.
Aq. menth . . . . . ʒ 1.

The cavity of the throat was sprayed with this every three hours.

Thirty-one cases were so treated, with but one death. No ill effects were observed from the treatment except-ing salivation, which was not severe, and persisted only three or four days.

The temperature fell under the treatment.

As to the amount of fluid which could be safely used, one drachm of the fluid is enough for one application. When a solution of 1 to 2000 was used, fifty inhalations would give a maximum dose, of one and a half grains of sublimate, for an adult.

In children older than six years, 1 to 1000 solution was used; for children between two and six years, 1 to 2000; in children under two years of age, 1 to 4000 or 1 to 3000.

Inhalations with a hand-spray are best given for the first five times, hourly; then for five times every two hours; then every three hours until the symptoms are mitigated.—*Therapeutische Monatshefte*, April, 1887.

Coca Cigarettes.—Dr. Nachtigall confers on the excellent properties of coca, especially of the wine, in alleviating hunger, stimulating the system, etc., which properties manifest themselves especially when taken while on a long march or while enduring other hardships. Later on, he recommends an entirely new preparation of coca—the cigarettes. In his discourse he says that, first of all, the very agreeable and mild taste and odor of coca, which admirably adapts it to this preparation, deserve mention. After he himself and some of his acquaintances tried them, he gave them to asthmatics; then he used them for catarrhal affections of the respiratory organs, and also for megrim of the nervous form. He is of the opinion that the good practical results which he invariably obtained were due to the anæsthetic action of the coca smoke upon the nerves of the relative mucous membrane. No disagreeable after-effects were noticed, so that persons who are susceptible to the action of nicotin in ordinary tobacco can smoke them with impunity. The doctor is convinced that these cigarettes will soon supplant those made of belladonna, hyoscyamus, stramonium, etc., and strongly urges a trial of them.—*Pharmaceutical Record*, June 15, 1887.

The Treatment of Chronic Eczema of the Vulva in Children.—Apply three times daily a two per cent. solution of carbolic acid to the affected parts.

Once each week touch the diseased surfaces with ordinary acetic acid.

If ulceration occurs and becomes of some depth apply a dressing of

Iodoform (finely powdered) . . 1 part.
Alum . . . . . 2 parts.
—*Journal de Médecine*, June 26, 1887.

Painless Evisceration of the Eyeball.—Dr. Mules, of Manchester, describes the following simple procedure in the *British Medical Journal* of June 4, 1887:

The pain is due to a rapid pouring out of serum into the subscleral space, with subsequent infiltration and tension of the orbit; it is a pressure, not an inflammatory pain. To avoid this, after completing all the steps of the operation as hitherto conducted, cut the external canthus, burrow freely back into the orbit with a pair of sharp scissors to the back of the sclera, taking special care to open the subscleral space; introduce an antiseptic-ised horse-hair drain, the cut ends just passing through the cut canthus; apply a dry, thin, absorbent pad, and an ice-bag over all.

Opium and Bismuth for Diarrhœa:

℞.—Bismuth. subnit. . . . . ʒ 2½.
Opii (crude) . . . . . gr. 3.
Essent. anisi . . . . . gtt. 2.
Div. in chart. 10 in number.
Sig.—One or two powders daily, before meals.
—*Journal de Médecine*, June 26, 1887.

A Neutral Hydrochlorate of Quinine.—Clermont has obtained this useful salt by combining the neutral sulphate of quinine in solution with a solution of barium chloride, and filtering to remove barium sulphate formed. The liquid thus obtained, when evaporated at 100°, furnishes the neutral hydrochlorate; a salt which

is easily dissolved in its weight of water at ordinary temperature, and not being caustic, is well fitted for hypodermatic use. At a temperature lower than 5° C. the solution deposits crystals which dissolve at 15° C.—*Bulletin Général de Thérapeutique*, June 15, 1887.

CHOLERA CONTAGION CONVEYED BY MILK.—DR. SIMPSON, Health Officer at Calcutta, reports the following case in the *Indian Medical Gazette* for May, 1887, which we abstract as follows:

The following outbreak of cholera on board the ship "Ardenclutha," is interesting as showing how localized outbreaks in widely scattered parts of a town may break out simultaneously, and, though seeming to have no connection, may have a common origin which is neither due to any climatic condition, nor to a peculiar epidemic state of the atmosphere, but to taking into the system a something which has been polluted by cholera excreta.

Hearing from Dr. Birch that several cases of cholera had been admitted into the General Hospital of Calcutta from one of the ships moored in the river, it occurred to me that a good opportunity presented itself of investigating the cause of the outbreak. On visiting the ship we found that not only had there been five cases of cholera, but we were informed that a number of the crew had been suffering from diarrhœa, and the general impression was that the outbreak was due to entrance into the cholera zone and breathing a cholera air.

1. On investigation we found an outbreak of cholera on board ship which was traceable to the use of milk supplied by a certain milkman.

2. The milkman, who acknowledged and is known to adulterate his milk, dwelt in a hut at Howrah, adjacent to and in immediate vicinity of a cholera polluted tank.

3. A localized outbreak of cholera traceable to a tank polluted with cholera excreta.

From this inquiry I think it may be safely inferred that it is in the highest degree probable that the two simultaneous outbreaks of cholera, the one in Howrah on the land, and the other in the ship in the river, were due to the one and the same cause; that the patients who suffered on board ship and at Howrah had done so in consequence of having taken into their system (swallowing) some cholera poison previously contained in the dejections of a cholera patient; that in the case of the Howrah outbreak the medium for conveying the cholera poison was the water which had previously been polluted; that in the case of the outbreak on board ship the medium for conveying the cholera poison was the milk which previously had water added to it containing the cholera poison obtained from a cholera patient; and lastly, that the connecting link between the two outbreaks was the milk. This investigation also shows how cholera prevailing at a distance may establish itself simultaneously at two widely different places, and yet may be due to a common cause which is preventible.

APOMORPHINE AND MORPHINE IN WHOOPING-COUGH.—DR. P. F. FEDOROFF, of Arkhangelsk, states (*Proceedings of the Arkhangelsk Medical Society*, part 2, 1887, p. 92) that he has obtained good results in whooping-cough by the internal use of the following mixture:

R.—Morphin. muriatic. . .	gr. ij.
Apomorphin. muriatic. . .	gr. j.
Acid. muriatic. . . .	℥ss.
Aq. destill.	℥viij.—M.

S.—A tablespoonful four times a day.

The paroxysms are lessened both in number and frequency after the first few doses of the mixture.—*British Medical Journal*, July 9, 1887.

PURULENT PERITONITIS CURED BY INCISION AND DRAINAGE.—In the *Revue Médicale de la Suisse Romande*, of May 15, 1887, p. 291, DR. E. CEPPI, of Porrentruy, publishes a remarkable case of chronic purulent peritonitis in a previously healthy and robust woman of twenty-nine, which was cured by abdominal incision with drainage. The disease proved to be of gonorrhœal origin, small accumulations of Neisser's gonococci being found in the pus-cells. Similar microbes (diplococci consisting of ovoid cells measuring 0.85 *u*) were discovered also in the purulent discharge from the uterus. This case is the first in which the gonococcus has been found in the peritonitic exudation.

THE BEST MATERIAL FOR NERVE SUTURE.—MR. BOWLBY, of St. Bartholomew's Hospital, writes as follows in the *Lancet* for July, 1887: "The choice of a material for suture is naturally influenced by the same considerations as those which obtain in the similar operation of ligature of vessels, and just as in the latter it is advisable to use a tissue which will not act as an irritant and will be absorbed, so is a similar material indicated in the suture of nerves. In the majority of recorded cases catgut has been used, and I am inclined to consider that for small nerves carbolized catgut is the best material. In those cases, however, in which there is any unusual tension, or in which it is anticipated that, on account of any complication, it may be necessary to disturb the wound, I think that carbolized gut does not possess the proper amount of resisting power, and does not last a sufficient length of time. In such cases I should use by preference a more stable ligature, such as chromicised catgut, kangaroo tendon split into sufficiently small filaments, horsehair, or fine silk; I prefer the two former to the latter. After apposition has been obtained by suture, the limb should be fixed on a splint in such a position as to keep the injured nerve in a state of the least possible tension. The wound should be thoroughly cleansed, all sutures used should be first rendered aseptic, and every endeavor should be made to insure healing by first intention."

COCAINE IN EVACUATING HYDROCELE.—DUBUC used the following with advantage in a case where it was not desired to use an anæsthetic in puncturing a hydrocele. After the injection of this fluid the contents of the sac were evacuated and iodine was injected; the procedure was painless.

Aquæ destillat.	100 parts.
Cocaine hydrochlorat. . . .	1 part.
Boric acid (pure)	3 parts.

—*Annales des Maladies des Organes Génito-Urinaires*, July, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.

Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,

Philadelphia.

SATURDAY, AUGUST 13, 1887.

THE RESULTS OF GASTRO-ENTEROSTOMY.

In our issue of July 23d we took occasion to consider the results of pylorectomy, and we now wish to present the results of the allied operation of gastro-enterostomy. Both procedures have for an object the reëstablishment of the continuity of the alimentary canal, or rather the relief of stenosis of the pyloric orifice. The first operation aims to be radical in its effect, the second only palliative. We endeavored to show in our last article that, as a matter of fact, neither operation was radical, and that the one which was attended with the least mortality, and the greatest amount of respite to the greatest number, was the one to be preferred.

Since the above opinion was expressed, an elaborate and highly interesting article has appeared in the *Deutsche Zeitschrift für Chirurgie* of June 22, 1887, from the pen of Dr. C. Rockwitz, of Strassburg, in which the results of gastro-enterostomy at the Strassburg Clinic are detailed, and the whole subject carefully considered. Altogether the operation has been performed 29 times, with 16 recoveries from the operation, and 13 deaths. Of these cases, 8 were performed by Prof. Lücke, of Strassburg, with 7 recoveries and 1 death, a success which is phenomenal. We thus see that 55 per cent. of the cases operated on have survived the operation, and 45 per cent. have perished, which affords a marked contrast to pylorectomy, which has a mortality of 72 per cent. when performed for all causes. When performed for carcinoma, gastro-enterostomy has proved fatal in 60 per cent. of the cases, and 40 per cent. have survived for longer or shorter periods. For cicatricial stricture, but 1 death resulted in 7 cases, and the most of those who recovered were radically cured, and were freed from their distress and suffering.

In presenting any statistics in regard to the mortality of gastro-enterostomy, it must be remembered that in almost every case the operation has been performed for conditions which precluded resection of the pylorus; hence the mortality is far in advance of that which is inherent to the procedure; and, likewise, the continuance of the benefits in those who survived is materially shortened for the same reason. Of the 16 cases which recovered, 2 died in one month of marasmus, but with a respite from suffering for that length of time; 1 who was suffering from tuberculous ulceration and stricture of the duodenum, died of marasmus and peritonitis in two months, after having gained 11 pounds in weight during the first month; 1 died in three months, of marasmus; 1 in four months, after gaining 11 pounds in weight; 1 in five months, after gaining 5 pounds; 1 in six months; 1 in fourteen months, after gaining 7 pounds in nine weeks; whilst Rydygier reports one case alive and well seven months after operation undertaken for ulcer of the duodenum; and a second case radically cured from the effects of a cicatricial stenosis of the pylorus.

Socin, after resecting the pylorus for cancer, subsequently performed gastro-enterostomy, with the result of again relieving his patient from her sufferings, and with the gain of 11¼ pounds in four months. Lücke reports one case, operated on for a tumor of doubtful nature, well at the expiration of one year, and increased in weight 15 pounds; another case, by the same surgeon, as well and 3 pounds heavier, thirteen months after operation; and a third case, alive, well, and with a gain of 39 pounds, eighteen months subsequently. The best result yet reported, however, is that of Hahn, who performed the operation two years ago for supposed inoperable cancer, the patient surviving and being not only in good health, but about 54 pounds heavier than before the operation. One case is reported as having been discharged cured in thirty-seven days, and as the operation was for cicatricial stenosis, the result is probably permanent.

We see from the above-mentioned cases, that gastro-enterostomy, whilst it does not secure radical cures in the case of cancer, does palliate the distress to a remarkable degree, and in the case of cicatricial stricture it circumvents the stenosis and restores the patient to a condition of permanent health. As has been stated, the operation has generally been performed as the *dernier ressort*, frequently after attempts at removal, which have materially complicated the case.

We hold that resection of the pylorus is only to be thought of when there are no adhesions to surrounding parts, and when the lymphatic glands are

but slightly involved; in all other cases gastro-enterostomy ought to be performed as a primary operation without any previous attempts to break up the adhesions. If we examine the causes of death after this operation, we find that eight died of collapse and exhaustion in less than three days. One died of internal hemorrhage from the wound and one from peritonitis on the fourth day, whilst one died from exhaustion on the tenth day, due to vomiting caused by the formation of a spur, which obstructed the efferent limb of the bowel. Peritonitis and exhaustion caused the death of two cases on the twelfth and eighteenth days respectively.

As has been stated, the results of gastro-enterostomy as performed by Prof. Lücke are of the most surprising character; not only is his mortality very low, only 12.5 per cent., whilst that of other operators has been over 57 per cent., but the benefits secured by him are also brilliant, one patient with a non-malignant tumor being well one year after operation, another with cicatricial stenosis entirely relieved, whilst one woman with carcinoma survived the operation fourteen months, besides other cases which lived in comparative comfort for short periods.

The reason for the better results of Lücke is not very apparent, but appears to be due largely to the fact that he does not attempt resection of the pylorus if there are any adhesions to surrounding parts, or much glandular involvement, hence, the parts are in a very much better condition for gastro-enterostomy than when a great deal of manipulation has been unsuccessfully done. Another factor is his method of suturing, about eighty sutures being used in most cases, which secures accurate apposition of the edges of the fistula. Stress is also laid on the importance of seizing the first convenient coil of small intestine, instead of searching longer and disturbing the relation of parts in the manipulation necessary to find the first portion of the jejunum. Whatever the explanation may be, the fact remains that Lücke's results put those of all other operators in the shade. In some of the above cases prolonged vomiting, which eventually became stercoraceous, occurred, and marked benefit followed copious irrigations of the stomach.

The article of Dr. Rockwitz is one which will repay a careful study, but we can only cite the more important of his conclusions in regard to the method of operating. 1. All separation of adhesions, isolations, and manipulation in the abdominal cavity ought to be carefully avoided. 2. Previous preparation of the patient is of importance for the success of the operation. 3. The incision in the linea alba is to be preferred. 4. Use the first convenient coil of intestine for the formation of the gastro-intestinal fistula, and avoid much searching and manipulation in the attempt to reach the plica duodeno-jejunalis. 5. The danger of compression of the colon by the mesentery of the raised small intestine is not sufficiently great to demand a complicated and dangerous modification in order to avoid it. 6. In the formation of the fistula employ the original simple method, as the formation of spurs and bends is not avoided by the more complicated procedures. 7. In order to secure a good functional action, the peristalsis of the bowel must correspond to that of the stomach. 8. For the formation of the fistula less depends upon the method of suture than upon its exact and proper execution.

THE ACID CALCIUM PHOSPHATE TREATMENT OF TUBERCULOSIS.

So frequent is the occurrence of local tuberculosis, and so serious are its permanent results when joints are attacked, that a mode of treatment which promises not only the cure of the local disease, but avoids the loss of motion so often resulting after other treatments, is worthy of consideration and trial. In The Medical News of June 25, 1887, p. 710, we described Kolischer's treatment by the injection of acid calcium phosphate, as reported to the Academy of Physicians of Vienna. We are now in a position, from his later reports, to give our readers the details of his method, and his conclusions as to its value, based upon the study of 500 cases.

From the *Wiener medizinische Presse*, No. 24, we learn that the solution used by injection contains 6.5 per cent. of acid calcium phosphate, with 1 to 1000 of free phosphoric acid; for the saturation of gauze, which is used in tamponing tuberculous fistulæ and dressing tuberculous ulcers, a solution of 6.5 per cent. acid calcium phosphate containing 1 per cent. of free phosphoric acid is employed; the proportion of free acid is increased to 2 per cent. where an especially caustic effect is desired.

Previous to injection the surface of the diseased part is disinfected by mercuric chloride; the injection is made with a platinum needle introduced deeply into the tissues: if great pain results, cocaine may be added to the solution. The contents of a Pravaz's syringe may be given at one injection; all injections used were sterilized. The formulæ for these solutions will be found in the Progress columns of this issue of The News.

In the same issue of the *Presse*, Froschauer states that he was led, when studying the influence of phosphoric compounds upon anthrax, to infer their power to influence tuberculosis. He cites the carnivora as less liable to many infectious diseases than the herbivora, and explains this fact by the acid calcium phosphate which is produced in the decomposition of nitrogenous food, before the formation of destructive ammoniacal compounds occurs. He

reasons that the administration of the acid phosphate will increase the natural resistance of the carnivorous organism, and greatly assist it in its struggle with tubercular infection.

Kolischer's experience (*Wiener medizinische Presse*, July 17, 1887) leads him to consider his method especially valuable with children, in whom, in many cases, speedy cures result, while others recover after prolonged treatment and overcoming of tedious complications. In rare cases it is without effect. The gauze saturated with calcium phosphate solution has been found an excellent dressing material in the treatment of caries.

Patients at about adolescence are among the most favorable cases; those whose disease has resisted other methods of treatment, and in whom extensive caries exists, were generally cured in from three to four months. The percentage of unimproved cases among these patients was very small. In older persons persistent treatment was much less successful. When tuberculosis was deeply seated it was not influenced until suppuration had reached the surface, when free drainage and tamponing with the gauze were generally successful. External tuberculosis among the phthisical was rarely cured; cold abscesses could be emptied, tamponed, and healed, but the general infection was uninfluenced.

Albert, in whose clinic this treatment is in use, believes that it is a distinct advance in surgery, and is destined to improve markedly the results obtained in localized tuberculosis.

A NEW AID IN THE DIAGNOSIS OF GASTRIC DISEASE.

It is a point of capital importance in the diagnosis and treatment of diseases of the stomach, to determine the motor power of the organ, or, to be more accurate, the period that elapses between the entrance of food through the cardiac orifice and its exit through the pylorus. The chemical properties of salol have enabled Ewald (*Wiener med. Presse*, 1887, No. 28) to accomplish this desirable object. The decomposition of this substance, and consequent appearance of salicylic acid in the urine, does not begin until it has passed into the small intestine. Salol may be mingled with the contents of the stomach and kept at the temperature of the body for hours without decomposition. This fact was determined by Ewald in twenty-five experiments. On the other hand, it is rapidly decomposed in the alkaline secretions of the intestine. In healthy persons salicylic acid appears in the urine in from one-half to one hour after the administration of salol. If this limit is overstepped, the delay may be attributed to pathological changes in the stomach. In eight typical cases of dilatation of the stomach studied by Ewald, salicylic acid could not be found in the urine until from two to three hours after the ingestion of salol, and in two obscure cases the same observer was enabled to detect dilatation by means of this delayed reaction.

This interesting observation is applicable, not only as a means of diagnosis, but as a test of the effect of treatment; for, by means of it, Ewald has been enabled to determine that both electricity and massage hasten the passage of the chyme into the intestine.

THE VALUE OF STROPHANTHUS HISPIDUS IN HEART DISEASE.

The very fact that this drug came before the profession of this country and abroad with the recommendation of Fraser, of Edinburgh, is to a certain extent a guarantee of its value, and nothing except its scarcity has retarded its more general use. Fortunately, the price has been reduced considerably since the first rush for its possession has passed away, and it now stands ready to enter our list of remedies, there to be tested side by side with its older fellows.

While the profession in general have as yet had but slight opportunity to test this drug for themselves, it has been tried with favorable results by Dana and Smith in New York, and by quite a large number of clinicians in England and on the continent. In the June and July numbers of the *Therapeutische Monatshefte*, Dr. Emil Pins, of Vienna, has an interesting clinical report regarding its value. Before calling further attention to his results, however, we will remind our readers that, according to the studies of Fraser and Brunton, this drug is nearly identical with digitalis in its action on the heart and blood-vessels, and in its influence on the secretion of urine. It contains an active principle, which is a glucoside, and is called strophanthin, but which has not been generally used, the tincture of the seeds being most commonly employed.

Pins has found that this tincture acted admirably in those cases of cardiac failure depending more particularly on valvular disease, and produced the most desirable results where the lesions caused dropsy and consequential need of increased renal action. Under the use of strophanthus the pulse, heretofore weak, rapid, irregular, and flurried, became slower and more powerful while the anasarca steadily decreased. In cardiac dyspnœa, both direct and indirect in its causation, it relieved the patient, and in every way proved itself to be the equal of digitalis. The belief reached by Dr. Pins is that strophanthus is eminently a heart tonic, and is especially useful in cases of chronic Bright's disease, and he also agrees with all the other recorders of bedside studies with this drug, that its diuretic properties are of great value.

The practitioner has heretofore often found to his alarm that his patient has gradually become somewhat accustomed to digitalis, so that the dose has

to be constantly increased, and has sorely felt the need of some drug which might possess similar powers. So much reliable evidence has now been brought forward as regards strophanthus, that it would seem that such a drug has at last been found, and the thanks of the profession are once more due to Professor Fraser for his last addition to our knowledge of therapeutical agents.

THE Illinois State Board of Health, at a recent meeting, passed a resolution which defines "medical colleges in good standing" in Illinois as follows:

Resolved, That the phrase "medical colleges in good standing," in the first section of the Act to Regulate the Practice of Medicine, approved June 16, 1887, is hereby defined to include only those colleges which shall, after the sessions of 1890–91, require four years of professional study, including any time spent with a preceptor, and three regular courses of lectures, as conditions of graduation, and shall otherwise conform to the Schedule of Minimum Requirements heretofore adopted by the Board.

THE enticing yellow tea-bun is not the only article of diet that is enriched with chrome yellow. Maccaroni and vermicelli are frequently found in the shops tinctured with this same derivative of lead; and these are sold to the unwary under the trade appellation of "egg-maccaroni," and the like. It is needless to say that this is a rank deception and fraud, and dangerous in the proportion that it deceives. Health officials should confiscate these "egg-foods" wherever found. Highly colored candies, and yellow sugar used for decorative purposes, have been found, also, to owe their attractive color to the fatal chrome yellow.

A PRELIMINARY programme has been announced for the meeting of the International Medical Congress. The Congress will be opened on Monday morning, September 5th, in the presence of the President, the report of the Secretary General submitted, and an address of welcome will be delivered by the Secretary of State, the Hon. Thomas F. Bayard. In the evening a conversazione will be held at the Pension Office. General meetings will be held on each morning of the week, and meetings of the sections will also be held on each day except Saturday.

Addresses will be delivered in general session, by Dr. Austin Flint, of New York, on "Fever, Its Causes and Rational Treatment;" by Dr. Mariano Semmola, of Naples, Italy, on "Bacteriology and Its Therapeutical Relations;" by Dr. P. C. Unna, of Hamburg, Germany, on "The Relations of Dermatology to General Medicine;" by Dr. C. Fielding Blanford, of London, on "The Treatment of Recent Cases of Insanity in Asylums and in Private Houses;" by Dr. A. Lutaud, of Paris, on "The Influence of Discoveries of American Surgeons on the Development of Gynecology in Europe;" and by Dr. Neudorfer, of Vienna, on "The Military Medicine of the Present and that of the Near Future."

The social features of the meeting will be a reception by citizens on Wednesday evening, a general reception and buffet banquet at the Pension Office on Thursday evening, and a trip to Mount Vernon on Saturday afternoon.

A Bureau of Information has been established in the Hoffman House, New York, for the benefit of delegates from foreign countries.

THE Marine-Hospital Bureau is informed that smallpox and yellow fever are raging in Havana, Cuba. During July there were 104 deaths from yellow fever, and 112 from smallpox.

SOCIETY PROCEEDINGS.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-third Annual Meeting, held at New London, Conn., July 20 and 21, 1887.

(Specially reported for THE MEDICAL NEWS.)

(Concluded from page 162.)

RETINITIS PIGMENTOSA TREATED BY ELECTRICITY.

DR. M. STANDISH, of Boston, reported a case. The patient was a woman, aged thirty-three, myopic 1.50 D. She had worn correcting glasses since seventeen years of age. When first seen, in April, 1886, her sight had been failing for three years, for the last three months very rapidly, so that she could not go on the street alone after dark. Upon ophthalmoscopic examination characteristic patches of retinitis pigmentosa were found in the periphery of the fundus in each eye. Her vision was right, $\frac{12}{XL}$; left, $\frac{12}{L}$; and the fields of vision were limited to less than 20° in the vertical and horizontal axes. The only treatment had been the use of the constant current, of such strength as could be easily borne. This has been applied, once in five days, during the last fifteen months. The present vision is, right, $\frac{12}{XXX}$; left, $\frac{12}{XV}$; and the fields have now vertical and horizontal axes of 70°. She now goes on the streets after dark with safety.

DR. H. DERBY, of Boston, reported a case in which there was poor vision, greatly contracted fields, and a large amount of pigment in the fundus, blue being the only color recognized. Under similar treatment, central vision improved, the fields widened, and the perception of red and green was reëstablished.

ASEPTIC CATARACT EXTRACTION WITH IRRIGATION.

DR. C. H. WILLIAMS, of Boston, reported five cases of irrigation of the anterior chamber, after cataract extraction, with a one-half per cent. solution of chloride of

sodium, as recommended by Dr. McKeown. Instead of a syringe, a glass flask was used, having a capacity of 50 c. c. Two glass tubes were blown into the sides of the flask, one being drawn out to form a nozzle, which could be easily inserted into the anterior chamber; and the other, having a rubber tube and mouth-piece attached, so that the force of the stream could be easily controlled by the operator; and the flask holding enough fluid to complete the irrigation without withdrawing the tube. The irrigating instruments, and the two per cent. solution of cocaine, were sterilized in a steam sterilizer. This was not found to injure the anæsthetic properties of the cocaine. The rest of the instruments and the dressings were sterilized by dry heat at 150° Cent. To determine the efficiency of a solution of biniodide of mercury, used for a preliminary washing out of the conjunctival sac, some experiments were made with plate cultures, at the laboratory of the Harvard Medical School, through the kindness of Dr. Ernst. Equal amounts of the biniodide of mercury and iodide of potash were dissolved in water, and added to 10 per cent. nutrient gelatine, to give a series of strengths up to 1 to 5000 of the biniodide to the gelatine. Ten days after exposure no growths of bacteria were found on any of these plates; although on unprotected plates, exposed at the same time, there was an abundant development of colonies of bacteria. Gelatine of the strength of Panas's solution (1 to 20,000) of the biniodide, showed after four days an average of 1.5 and 0.8 colonies of bacteria to the square centimetre of surface in two series of plates, while on unprotected plates, exposed at the same time, the average was 10.7. In two of the cases of extraction a suture was passed through the small piece of conjunctiva left at the apex of the corneal flap, to unite it to the conjunctiva above. This was found to hold the wound well in place. All the extractions were done without iridectomy; and a layer of iodoform was dusted along the edge of the closed eyelids just before applying the bandage.

Dr. L. Howe thought that we must learn the special resistance to microbicides, of each particular kind of bacteria. Then, again, experiments with pathogenic bacteria, made in the rabbit, may not indicate their effect on man. And their action on different parts of the same organism may be different. Bacteria that are dangerous when introduced within the eye may be comparatively harmless in the conjunctival sac.

Dr. E. Gruening had done within a year 16 extractions without iridectomy. In 11 cases a perfect pupil was secured; in 7 the iris had to be removed subsequently, or synechiæ were established. He washed out the conjunctival sac with a saturated solution of boric acid. Being able by manipulation to get this sucked into the wound in sufficient quantities, he had not used direct irrigation of the anterior chamber. No eye had been lost. He had also done 13 extractions with iridectomy during the same period.

CASE OF CONGENITAL, ZONULAR OPACITY AROUND THE FOVEA.

Dr. O. F. Wadsworth, of Boston, reported a case occurring in a female infant, aged eleven months, the sixth child of Jewish parents; first four healthy, the fifth had died when eighteen months old. The mother had been sick while carrying the last two children. Father healthy. Its muscular system seemed undeveloped, and it took but little notice of things around it. During the first ophthalmoscopic examination it fixed its eyes on the mirror. The greater part of the fundus appeared normal, as was the fovea. Around the fovea was a zone of a diameter one and a half times that of the disk, of light-gray opacity, over which the smaller branches of the retinal vessels could be seen. Five months later the child took no notice of the mirror, or anything else. The optic disks were gray and devoid of small vessels. The pupils responded very faintly to light, and the child had grown thinner, muscles still undeveloped.

Dr. H. Knapp said that the case is a rare and characteristic one, of what appears to be a general arrest of development of the cerebral cortex. A case he had seen improved apparently during last summer, but in winter grew worse and died. The disks, which early in the case were pale, later became completely atrophic. An autopsy showed marked change in the cerebral cortex; and an arrest of development of the whole nervous system. He believed such cases would be more frequently recognized if ophthalmologists saw more of the cases of brain disease in infancy.

ALBUMINURIA OF PREGNANCY, SEPARATION OF BOTH RETINAS, REPLACEMENT.

Dr. O. F. Wadsworth had seen the case of a woman seven and one-half months pregnant, with œdema of the lids, urine loaded with albumen and containing casts; indistinctness of vision was found to be attendant on extensive separation of the retina in both eyes. After the use of one-sixth of a grain of pilocarpine hypodermatically, portions of the retinas became reapplied. The dose was repeated and the retina became still more generally replaced. At the same time it became more affected with grayish opacity. Premature labor occurred with convulsions; and unconsciousness continued sixty hours, at the end of which time only movements of the hand before the eye could be seen. Two weeks later vision was improving, but there was extensive grayish opacity with patches of white exudation and small hemorrhages in the retina. Six weeks later there was no separation of the retina, and vision=right Jäger 13, left Jäger 5. Since that time it is stated that her vision has gradually improved.

Dr. S. D. Risley thought there were cases of retinitis connected with the albuminuria of pregnancy, that we were not justified in allowing to proceed to term. He had reported one last year. Since then he had seen another where only the shadow of the hand could be perceived. This patient soon after aborted spontaneously in the sixth month. This was attended with unconsciousness, followed by aphasia. But the intense swelling of the retina and snow-bank exudation has entirely disappeared; and there has been great improvement of vision.

COLOBOMA OF THE IRIS, CHOROID, AND OPTIC NERVE.

Dr. B. A. Randall presented drawings of three cases. It had been claimed that so-called underlying conus was a variety of coloboma; but one of these cases presented both coloboma and underlying conus. In one the disk seemed to present a second *porus opticus*. In another the bottom of the coloboma of the nerve

presented a refraction 13 D. higher than the neighboring fundus.

A PECULIAR FORM OF GRANULAR CONJUNCTIVITIS ASSOCIATED WITH ICHTHYOSIS.

Dr. F. Buller, of Montreal, reported two cases; both occurring in boys suffering from ichthyosis. The first, aged fifteen, had suffered from rheumatism and iritis. two years before, and six months later asthenopia. His parents were healthy and free from any skin affection, as were four older children; but two brothers younger than himself had the same condition of skin. The second was seven years old, and had weak eyes for two or three years. Parents free from skin disease. There was hyperæmia of the ocular conjunctiva. Compound hyperopic astigmatism. With correction, vision $= \frac{6}{6}$. In both the conjunctiva of the lower lid was swollen, smooth, pale and glazed, and presented tenacious yellowish mucus. The upper lid was thickened, and its conjunctiva pale and smooth, but presenting flattened elevations, some mushroom shaped, semi-transparent, containing minute red dots, and extremely hard. Microscopical examination showed these masses to consist of highly developed granulation tissue, mainly white fibrous tissue. The first case was treated for a year with the various remedies for trachoma without benefit. He had seen other cases, presenting the same local lesions, which remained equally rebellious to treatment; but they had not been examined for skin disease. There seemed to be not the least tendency to acute exacerbations. The secretion from the conjunctiva was entirely different from that of ordinary trachoma. In the family of each there were several children, and none of the others had showed any affection of the eyes; so it could not be contagious. The changes were most characteristic on the upper lid, where the structure of the conjunctiva most nearly resembles that of the skin. He proposed that this affection should be called *ichthyosis of the conjunctiva*.

MODIFICATIONS OF THE OPHTHALMOSCOPE.

Dr. W. S. Dennett, of New York, showed his electric light attachment, or handle, for the Loring ophthalmoscope. It could readily be fitted to other forms of the instrument. Also a cheap and satisfactory battery for supplying the current for it or for the galvano-cautery. He found it much easier for beginners to get a good view of the fundus with the electric lamp as the source of illumination; and that the light was better and more manageable.

Dr. L. Howe showed an ophthalmoscope with a good lens disk which packed together into the compass of a small pill-box.

Dr. S. D. Risley presented an ophthalmoscope with cylindrical lenses. He had modified Loring's ophthalmoscope by adding two slides, like those proposed by Dr. Jackson, which moved just back of the mirror. These contained convex cylindrical lenses with their axes parallel to the stem of the instrument. One slide contained 0.50, 1, 1.50, 2, and 2.50 D., and the other 0.25, 3, 4, 5, and 6. With these 0.25 D. intervals were obtained up to 3 D., and 0.50 D. intervals to 8.50 D. The spherical lenses were the same as those in the common form of Loring's ophthalmoscope with the accessory quadrant. The direction of the cylinder axis could readily be changed by merely varying the direction of the handle from the perpendicular. It was well known that in most cases of astigmatism the meridian of greatest refraction was vertical or very nearly vertical; and even when it was at right angles to this the cylinder could be adjusted to it. Some weeks' use of the instrument had shown it was capable of doing all he had expected of it. The instrument had been made by Queen & Co., of Philadelphia.

Dr. S. M. Burnett, of Washington, presented an ophthalmoscope with modifications, consisting, first, in a clip on the back of the instrument, in which the cylinders from the cases of test lenses can be inserted. A graduation around the edge of the mirror-plate shows the inclination of the axis of the cylinder. This, he claims, is very useful for verifying the diagnosis of astigmatism by other methods; and also enables us to see the fundus of an astigmatic eye free from its anomalous refraction. Second, two superimposed disks containing lenses which, singly and in combination, give 47 numbers (22 plus and 25 minus), with a regular interval of 0.5 D, up to 10.5 D. Third, a plane circular mirror, in front of which is swung a tilting mirror. The plane mirror does not interfere with the tilting mirror when in use; and when it is desired to use the plane mirror alone, the tilting mirror can be detached from its upper bearing, and will swing on its lower bearing, out of the way. The instrument is very light. It is made by Queen & Co., of Philadelphia, and its cost is about twenty dollars.

Dr. O. F. Wadsworth had for several years used a clip on the back of his ophthalmoscope to hold cylindrical lenses, and thought that Dr. H. D. Noyes had shown such an arrangement before the Society.

Dr. Burnett did not claim originality; he had merely combined in convenient form what before had been used on different instruments.

Dr. E. Jackson thought that since astigmatism blurs the retinal image only about half as much as the same degree of hyperopia or myopia, and since 0.50 D. was the smallest interval of practical value between the successive spherical lenses of the refraction ophthalmoscope, that the interval between the cylinders should be a whole dioptre. The Loring ophthalmoscope might be modified by adding the two slides, removing the quadrant, and placing the four lenses from it in one slide; and, in the other, using 1, 2, 3, 4, and 5 D. concave cylinders with their axes perpendicular to the stem of the instrument.

Drs. W. S. Dennett and P. A. Callan had independently tried using a small Stokes lens back of the ophthalmoscope, but had abandoned it.

Dr. B. A. Randall was still using with satisfaction the arrangement of cylindrical lenses shown to the Society a year ago.

PHOTOGRAPHS OF THE FUNDUS OF THE EYE.

Dr. L. Howe showed a series of these obtained from the living human eye. The exposure was about fifteen seconds. The original negatives had to be very small to get an impression strong enough. These were subsequently enlarged. The great difficulty had heretofore been to get a formula for a plate sufficiently sensitive to the red rays returned by the fundus.

SMALL TEST LENSES AND TRIAL FRAMES.

Dr. E. Jackson exhibited a set of test lenses one inch in diameter. This decrease in the size of the lenses effected a reduction of more than one-half in the weight of lenses and trial frames. They were also made plano-convex and concave, giving less spherical aberration, making it easier to combine two of them, and capable of being used to neutralize accurately other lenses. Additional lenses were introduced. In the trial frames the temple was attached near the lower part of the lens-carrier, instead of opposite the middle, so that the lenses could be introduced and removed in the most convenient direction directly toward the temple.

CASES AND VERBAL COMMUNICATIONS.

Dr. Jackson presented, for Dr. C. A. Oliver, pictures of two cases, one of double chorio-retinitis, with partial degeneration of the optic nerve, associated with curious lymph extravasation into the retina and vitreous; the other, of coloboma of the iris, lens, and choroid.

Dr. D. B. St. J. Roosa offered the history of a case of recurrent paralysis of the motor-oculi, associated with migrane, in a young man, commencing at fourteen and increasing in severity.

Dr. John Green had noticed, after an attack of iritis, an increase in his own myopia of 1.50 D., which disappeared gradually after recovery. He had since noticed the same thing in some of his patients, and believed the myopia to be a consequence of the iritis.

Dr. O. F. Wadsworth had observed the same phenomenon.

Dr. B. A. Randall had been consulted by a man, aged twenty-two, with myopia of 2.50 D., who complained of a spot before the right eye, which had first been noticed ten days before. He found a moderate choroidal trouble and a well-marked posterior polar cataract. He could not believe it to be of such recent origin until during the succeeding month, when it changed rapidly in shape, extended, and became obscured by a similar opacity starting on the anterior surface of the lens. Apparently there was no increase of myopia.

The following were

ELECTED MEMBERS:

Drs. J. B. Emerson, of New York; H. F. Hansell, of Philadelphia; J. O. Tansley, of New York; T. Y. Sutphen, of Newark, N. J.; M. H. Post, of St. Louis; E. C. Rivers, of Denver City, Col.; George R. Cutter, of Brooklyn; D. C. Cocks, of New York; H. S. Oppenheimer, of New York; Charles McIlwaine, of Trenton, N. J.; David DeBeck, of Cincinnati.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. William F. Norris.
Vice-President.—Dr. Hasket Derby.
Secretary and Treasurer.—Dr. O. F. Wadsworth.
Corresponding Secretary.—Dr. J. S. Prout.

To represent the Society in the Executive Committee, to arrange for the Congress of American Physicians and Surgeons, at Washington, in September, 1888, Dr. William F. Norris was chosen, and Dr. D. B. St. J. Roosa, alternate; with the proviso that such action did not bind the Society to approval of all the details of the present outline plan for such meeting.

The Society adjourned to meet at the Pequot House, New London, Conn., on the third Wednesday of July, 1888.

CORRESPONDENCE.

LETTER FROM STRASSBURG.

Kephir—Acute Osteomyelitis—Fracture of the Skull—Gastro-enterostomy.

A substitute for koumiss is coming very generally into use here and in Switzerland, which has the great advantage that it can readily be made in any place, and those who have used it largely speak very highly of it. It is the kephir of those Tartars who, having no horses, are dependent upon cows' milk from which to manufacture their milk-wine. Kephir is the product of the fermentation produced in milk by the presence of a peculiar ferment, when the fermenting milk is treated in a particular way. The method of its manufacture is kept as secret as possible by those who make a business of it. So successfully have they guarded their secret that when the hospital authorities attempted to make their own kephir, they were obliged to abandon the idea, as success did not crown their efforts.

Kephir contains less alcohol than koumiss, but is more nutritious. Kussmaul, Freund, and others here, are thoroughly satisfied with the results of its use, and are loud in its praise.

A man with an acute osteomyelitis in the head of the tibia was transferred from Prof. Kussmaul's department, to which he had been consigned as a case of pneumonia, to the surgical hospital. He had a few moist râles, a bloody sputum, and a slight consolidation, with an exceedingly high fever. The history was as follows: In attempting to jump from a street-car, while in motion, he fell on his knee, and bruised it against the paving-stones. The skin was scraped away from over the tuberosity of the tibia, but not to any great extent. At the time he paid no further attention to it, but on the second day he had a very severe chill. The symptoms of pneumonia, as above given, came on, and he was sent to the medical clinic. There the condition of his leg was noticed, and he was transferred to the surgical. He came in a semi-stupid, typhoid condition, with a morning temperature of 104½°. The leg was swollen, and highly inflamed, with deep fluctuation which could be readily determined in the upper part. It was now but the seventh day after the injury. He was given chloroform, and the collection of pus, which was situated between the periosteum and the bone, was cut into with great care, in order to avoid the joint. Several ounces of a thick, dark-colored pus escaped. The bone was denuded for a distance of two or three inches along the shaft. With a narrow chisel, an opening was made into the medullary cavity, where another collection of pus was found in a large abscess cavity, which was thoroughly cleansed and disinfected. A drainage-tube was drawn through the leg, a counter-opening having been made posteriorly, the entire leg enveloped in aseptic bandages, and the patient sent to the ward.

This was evidently a case of infection through the wound of the most acute character. The high fever was accounted for by the great pressure which both col-

lections of pus exerted upon their surroundings, and the lung symptoms to a possible secondary process in the lungs, due to the formation of fatty emboli.

A comminuted fracture of the side of the skull, complicated by fissures across the vault and base, was recently examined by Prof. von Recklinghausen, in the Pathological Institute. The man had fallen a distance of some twelve or fifteen feet, striking on the side of his head and right shoulder. Upon the third day he was brought to the clinic. All symptoms of concussion and compression had passed away. He spoke intelligibly in answer to such questions as were put to him, but a few hours later he died. There was a scalp wound on the right side of the head, some three inches above the ear. A large contusion, with subcutaneous extravasation of blood over the right side of the face, and consequent discoloration not only of the orbit, but of the entire half of the face. The shoulder and pectoral region of the right side were the seat of a similar contusion.

Prof. von Recklinghausen, as is his custom, gave with painful exactness a description of every external mark upon the body, as well as of all the pathological changes within. The main fissure ran in a half circle some two inches above the external auditory meatus, while three secondary fracture lines, branching out from this, passed across the vault, the one toward the orbit of the same side, another directly over the skull, almost to the external auditory meatus of the opposite side, while the third passed back across the occiput. Beneath the main fissure were several fragments, which were only held in position by the soft parts, and which were not depressed in the least. The largest was more than an inch long. Removing the skull-cap exposed a thin clot between the skull and the dura mater, in the region of the middle meningeal artery. The dura mater was torn in a line parallel to the artery, but a little behind it. Through this opening, the clot extruded, and was spread out in a thin layer over the brain. Here there was no destruction of the brain-tissue, but beneath the loosened fragments the dura was torn, and a superficial destruction existed. The hemorrhagic extravasation passed into the external end of the Sylvian fossa. Slight extravasations of blood were found in the right posterior and the left middle and posterior fossæ, between the skull and the dura mater. None of the cranial nerves were injured.

The fracture of the base was in the right anterior fossa, almost entirely. It passed around three-fourths of the periphery of this fossa, when it crossed the tip of the pyramidal process of the temporal bone, and circling around the foramen magnum, ended in the jugular foramen. A comminuted fracture of the outer third of the clavicle, and simple ones of the first seven ribs, completed the list of broken bones. The examination of the internal organs revealed nothing of interest, except a perforation of the parietal pleura by a splinter of the second rib, and an extravasation of blood in the anterior mediastinum.

This case is of interest when it is considered that after a careful examination the surgeon diagnosticated the fracture of the base, but not of the vault. The apparent damage to the brain was but slight in comparison to the injury of the skull. Usually with such extensive comminuted fractures there are symptoms of compression, or at least irregularities of the surface, that render the diagnosis easy. In this case the loosened fragments escaped the examining hand, not only of the surgeon, but also of the distinguished pathologist, who palpated the head with great care before beginning his dissection.

The report of Dr. Rockwitz, one of the assistants in the surgical clinic, upon the gastro-enterostomies which Professor Luecke has performed, is by far the most brilliant record that has been made in this operation. Curiously enough, the same number of cases have been operated upon as in the clinic of Prof. Billroth, where, it is well known, Woelfler first made the operation in 1881. In Vienna eight cases have been operated upon, of whom five died shortly after the operation. Of Prof. Luecke's cases not a single one died immediately after the operation. One died two weeks later, of pneumonia and inanition. The cases previously reported numbered twenty-two; or, if the first case of Luecke be excluded, but twenty-one. Of these, seventeen were for cancerous strictures, and four for non-cancerous. Of the first category, twelve died from the operation, a mortality of seventy per cent. In the second category there was but one death, a mortality of twenty-five per cent.

Luecke operated six times for cancer, and twice for stricture. The cancerous cases were between the ages of thirty and fifty. With the exception given above, they all recovered from the operation, and lived at least several months in comparative comfort. One survived the operation fourteen months. The last one operated upon was living when the report was made. Both cases of non-malignant strictures recovered, and seem to be permanently relieved; a mortality of but sixteen per cent. for the malignant cases against seventy per cent. from Billroth's clinic. Several of the cases were examined after death, and the relations of the intestines and the condition of the fistulæ were generally found to be satisfactory. In one case, however, the passage into the efferent arm of the loop of intestine was so distorted by cicatricial contraction that it was difficult to introduce a probe from the stomach into it. The adherent arm was distended with bile and pancreatic secretion.

The operation, which is necessarily tedious, lasted usually from an hour and a half to two hours. A portion of the stomach-wall was first selected that was free from bloodvessels. Two clamps with parallel arms are then so applied to a fold of the stomach as to prevent its contents from gaining access to the field of operation. In selecting the fold of small intestine, to be applied to the stomach, Luecke has never followed Woelfler, who directs that the upper end of the jejunum must be carefully sought for, and gives minute directions to be followed in securing the loop to the stomach-wall. All of this is regarded here as superfluous, and positively dangerous, as to follow these directions explicitly extends the time of the operation, and introduces new sources of failure. The rule here is to select the most convenient fold, and the object to establish a communication between it and the stomach as rapidly as possible. The result certainly justifies the teaching. A small portion of the selected fold is taken between the fingers, and emptied of its contents by gentle pressure. This portion is then secured in clamps similar to those placed upon the stomach. The formation of the opening and the union between the intestine and stomach are made as usual.

The twenty-nine reported cases give a mortality of

about forty-four per cent. from the operation itself. As this operation has proved so successful here, the tendency is to make it in preference to pylorectomy. This latter operation has never proved very successful, as its record of seventy-two operations for cancer, with an immediate mortality of fifty-five cases, or seventy-five per cent., conclusively shows. Therefore, Rockwitz would restrict the indications for the radical operation to that very small percentage of cases, the first class of v. Hacker's, in which we may hope for a permanent cure. The palliative operation has an immediate death-rate which is much less, and offers to all other cases as much hope as the radical.

Strassburg, July 11, 1887.

NEWS ITEMS.

Tenement House Inspection in New York.—The Health Department of New York City has set in operation a branch which is somewhat novel in sanitary work, as it unites the curative with the preventive practice of medicine. Thirty-seven young doctors, who have had their capacity established by the Civil Service Board, have been started out by the Health Department under orders to make house to house inspections of tenement houses, to discover if there are cases of illness which demand their attention, and to make a report on the sanitary condition of the premises. The doctors have authority to prescribe nourishing diet in addition to medicines, which are to be furnished free of cost when the family is too poor to pay for the supplies. Free passes to the excursions of the St. Johns's guild, are distributed at the discretion of these sanitary doctors. The city has appropriated $10,000 for this service and the number of physicians in the corps will be increased to fifty very soon. In sending out these young medical inspectors, Dr. Bryant, the recently appointed health commissioner, used these words: "Teach the poor people that you are their friends, and you will inspire them with confidence. Do unto them what you would expect to have done unto you under similar circumstances. Do not be carried away with the idea that you are a Board of Health representative and have great authority, but be gentlemen. If you find that some families, where a contagious disease exists, have employed a family physician, avoid making a diagnosis merely to confirm that doctor's views. Such a course is unprofessional and unmanly. Learn the origin of the disease and advise with the regular medical attendant, as to the best methods to be devised to check a spread of the disease among the families in the same house or neighborhood."—*Sanitary News*, July 23, 1887.

A New Hall of Anatomy at Vienna.—A large and completely equipped hall of anatomy will shortly be erected for the Vienna Institute. It will be lighted by electricity, and furnished with every convenience for research; its estimated cost will be $240,000.

Official Examination of Food in Russia.—A station is to be established in St. Petersburg for the examination of food materials offered for sale in the city. It will be under the charge of scientists appointed by the government.

Professor Virchow will attend the Congress of Hygiene at Vienna, and will spend the remainder of his vacation in Egypt, in company with Professor Schliemann.

Death by Opium Poisoning of a Celebrated Bone-setter.—Hutton, of Queen Anne Street, London, a noted bone-setter, took "black drops" by mistake, and died on July 16, 1887. He was a man of powerful development, noted for his skill in "bone-setting" in defiance of surgery, and by the manipulations known to his craft.

An Epidemic of Convulsions.—A curious outbreak of convulsionist mania, analogous to those which occurred from time to time during the Middle Ages, is reported to have shown itself at Agosta, in the province of Rome. For some weeks past the country people have been laboring under the delusion that the district is under the immediate government of the Evil One, and before retiring to rest they carefully place on the threshold the broom and salt, which are credited with the power of keeping off evil spirits. Many of the younger women have epileptiform attacks, during which they utter piercing shrieks, and are violently convulsed. So serious had the condition of things become, that the syndic of Agosta found it necessary to inform the Prefect, who sent detachments of soldiers into the district in order to calm the apprehensions of the inhabitants. The contrast between this strictly physical way of dealing with the disease and the more imposing but less effectual religious ceremonies formerly employed must be interesting to historical students. As a natural consequence of this condition of mental perturbation, the country is overrun with quacks who claim to possess the only infallible remedy for the seizures. One of these nostrums, the vender of which was making a rich harvest from its sale, was found on analysis to consist of earth, snuff, and borax. Three medical men who were commissioned to investigate the cause and nature of this extraordinary affection, came to the conclusion that it was an epidemic of hysteria. They examined a number of the sufferers, mostly young women, some of whom were alleged to have vomited nails, horseshoes, and other equally indigestible substance, while others barked like dogs. Several of them were removed to Rome for treatment in the hospitals there, and measures have been taken to check the spread of the mischief. In a milder degree, this contagious form of hysteria is not infrequent, especially in places where ignorance and superstition favor manifestations of nervous disorder. The worst excesses of popular outbreaks, like the French Revolution, have been attributed to similar influences, and with every appearance of justice.—*British Medical Journal*, July 23, 1887.

Secularization of Paris Hospitals.—By a vote of 64 out of 71, the Municipal Council of Paris has determined to instruct the Administration of Public Assistance to place five hospitals, now controlled by Sisters of Charity, under secular charge before January, 1888. Among these are the Charité and the Hôtel-Dieu.

Death from Antifebrin.—Dr. E. von Quast, of Kansas City, reports in the *Kansas City Medical Index*

a death which occurred in his practice from the administration of antifebrin in four grain doses every two hours during a day. The physician's orders called for one dose in the morning, an evening dose to be ordered by the physician, if needed, at his evening visit. Cyanosis and collapse were the fatal symptoms.

DEATH BY ELECTRICITY.—M. D'ARSONVAL has been conducting some experiments for the purpose of preventing fatal accidents from the use of electricity. He has come to the conclusion that electrical currents are not dangerous until a power of 500 volts is reached, and he has devised an ingenious plan by which the extra current which occurs at the moment the current is broken, and which is the chief source of danger, may be annulled or neutralized. A V-shaped tube, made of an insulating material, is filled with mercury and is interposed in the main current. In order to close the main current a tap is turned and the machine is unprimed without giving an extra current spark. Or a glass tube is filled with mercury and dipped into a reservoir containing mercury. This tube is provided with a ground stopper, which not only suppresses the extra current, but interposes any resistance in the current. The invention seems to be original and ingenious, but unless considerable care be taken, even with its assistance, danger is still imminent. Another observation made by D'Arsonval is that extra currents from the dynamic electricity and alternating currents do not produce serious organic disruption of the living tissues like discharges of statical electricity. This, however, is not a new observation. The special disruptive and fatal effect of the statical discharge has long been known in this country, and was most fully brought out in Dr. Richardson's experiments on death by electric shock conducted in the Royal Polytechnic Institution in 1869. In those researches sheep and other animals were killed by the statical discharge, and the cause of death was shown to be due to the sudden expansion of gaseous parts of the blood and tissues, by which organic lesions of the most extensive kind were induced. In one of this series of experiments the skull of a dead animal was fractured by the statical discharge, and arborescent markings of external veins, distortion of large veins, rupture of the heart, ecchymosis, rupture of the stomach, and decomposition of the blood itself, from the same kind of discharge, were phenomena traced to disruption from gaseous expansion. At the same time the statical discharge does not always kill. It may simply stun, or cause a temporary anæsthesia, or produce a state resembling catalepsy, followed by recovery.—*Lancet*, July 2, 1887.

SEPTICÆMIA AT THE PRESENT TIME.—DR. SENN writes as follows from Germany to the *Journal of the American Medical Association*, of July 2, 1887: "There is certainly a great deal of truth in the statement made by the famous Robert Koch, in answer to my question relative to the nature of septicæmia, that this disease is beyond the grasp of the pathologist in Germany, as antisepsis had succeeded in almost exterminating the disease in that country. I sympathize sincerely with the pathologists, but rejoice at the results obtained by Joseph Lister and his followers in expunging from the catalogue of diseases one of the most fatal and fearful complications of the obstetrical and surgical wards. In the face of these facts who can doubt any longer the efficiency of antiseptic precautions in preventing infection? Who will dare to ridicule the honest, conscientious surgeon and obstetrician in his efforts to protect his patients against infection? Who will have the courage to recommend a pad of infective germs as a safe dressing for penetrating wounds of the abdomen? Let history, science, and the combined experiences of thousands of honest physicians and surgeons answer these questions."

CARBOLIC ACID A SAFEGUARD AGAINST INSECTS.—Many people do not know how easily they can protect themselves and their children against the bites of gnats and other insects. Weak carbolic acid sponged on the skin and hair, and in some cases the clothing, will drive away the whole tribe. A great many children and not a few adults are tormented throughout the whole summer by minute enemies. We know persons who are afraid of picnics and even of their own gardens on this account. Clothing is an imperfect protection, for we have seen a child whose foot and ankle had been stung through the stocking so seriously that for days she could not wear a leather shoe. All this can be averted according to our experience, and that we believe of many others, by carbolic acid judiciously used. The safest plan is to keep a solution of the acid. The solution should not contain more than 6 or 7 per cent., and it may be added to water until the latter smells strongly. This may readily and with perfect safety, be applied with a sponge. We have no doubt that horses and cattle could be protected in the same way from the flies, which sometimes nearly madden them, and it even seems possible that that terrible scourge the African Tsetse fly, might be kept off in the same manner.—*Lancet*, June 25, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM AUGUST 2 TO AUGUST 8, 1887.

SUTHERLAND, CHARLES, *Colonel and Surgeon*.—Leave of absence extended one month.—*S. O. 174, A. G. O.*, July 29, 1887.

FRYER, B. E., *Major and Surgeon*.—Relieved from further duty at Fort Lowell, Arizona Territory.—*S. O. 176, A. G. O.*, August 1, 1887.

BROWN, HARVEY E., *Major and Surgeon*.—Relieved from duty in the Department of Missouri, and ordered to Jackson Barracks, La., for duty at that post.—*S. O. 174, A. G. O.*, July 29, 1887.

GARDINER, JOHN DE B. W., *Captain and Assistant Surgeon*.—Granted leave of absence for one year, on surgeon's certificate of disability.—*S. O. 177, A. G. O.*, August 2, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR TWO WEEKS ENDING AUGUST 6, 1887.

IRWIN, FAIRFAX, *Passed Assistant Surgeon*.—To inspect unserviceable property at New York Marine Hospital, August 5, 1887.

CARTER, H. R., *Passed Assistant Surgeon*.—Granted leave of absence for six days, August 1, 1887.

BEVAN, A. D., *Passed Assistant Surgeon*.—Granted leave of absence for ten days, August 5 1887.

NORMAN, SEATON, *Assistant Surgeon*.—Granted leave of absence for four days, on account of sickness, August 5, 1887.

ORIGINAL ARTICLES.

SEWER-GAS POISONING.

BY HENRY HUN, M.D.,

PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM, AND OF PSYCHOLOGICAL MEDICINE, ALBANY MEDICAL COLLEGE.

IN the houses of the present day containing all the modern improvements there is constant danger that the air from the soil pipes or drains will enter the house in consequence of defective plumbing; and that this danger is a very real one is shown by the frequency with which oil of peppermint, introduced into the drain of such a house, betrays itself by its odor in one or more of the rooms. Even a small leak in the soil-pipe, in consequence of the steady escape of sewer-gas, will suffice to contaminate a large air space, especially when the air is not rapidly changed —as, for instance, when the house is tightly shut up on a winter night.

Although it is a difficult thing to determine the exact cause of individual cases of disease, yet it is certainly a very widespread, if not a universal, belief in the medical profession that the escape of sewer-gas into a house may give rise to sickness. The mere fact that in a house with defective plumbing a certain form of disease occurs is, of course, no proof that the former is the cause of the latter. It may either be a mere coincidence, or the sewer-gas may predispose the system to, or even aggravate[1] the disease, without actually causing it. In order to make it probable that the defective plumbing, and the consequent escape of sewer-gas, is the cause of the disease, the two things must occur together many times, and the oftener that this concurrence takes place the stronger becomes the probability that there is a causal connection between them, and this probability becomes still stronger if, after the plumbing has been repaired, the disease more or less quickly disappears.[2]

The character of the sickness resulting from sewer-gas poisoning varies greatly, depending in part upon the different susceptibility to different diseases of the inmates of the house, and in greater part on the varying composition of the sewer-gas itself. An analysis of sewer-gas taken from well-ventilated sewers shows it to contain oxygen, nitrogen, carbonic acid, and ammonia in proportions not varying essentially from those of the atmosphere; and an analysis of sewer-gas taken from badly ventilated sewers (which is much more poisonous than that from well-ventilated ones) shows a diminution of oxygen, an increase of nitrogen, ammonia, and carbonic acid, and the presence of hydrogen sulphide, marsh-gas, and organic vapors of a carbo-ammoniacal composition. Large quantities of bacteria have also been found in sewer-gas.

Sewer-gas (which is merely a convenient name for the atmosphere of sewers) is, therefore, of a very complex and variable composition, and its toxic elements are not certainly known. In cases of acute asphyxia from very foul sewer-gas the symptoms so strongly resemble those of poisoning by hydrogen sulphide that this gas is probably the cause of such attacks; but it is very doubtful whether hydrogen sulphide is often present in a house in sufficient quantities to produce any poisonous effects. On the other hand, in cases of typhoid fever from sewer-gas poisoning the toxic element is doubtless the bacillus of typhoid fever, for which the sewer-gas acts merely as a vehicle, and it is probable that most of the cases of sewer-gas poisoning are due to pathogenic bacteria, which happen to be present in the sewer-gas, and are carried by it into the air of the house. It is probable that in all cases of sewer-gas poisoning the toxic element belongs in one or the other of the following classes:

1st. Pathogenic bacteria, which have already been isolated and studied, and may, therefore, be said to be "known."

2d. Pathogenic bacteria, which have not yet been isolated and studied, and are, therefore, "unknown."

3d. Poisonous gases, such as hydrogen sulphide.

The first two classes are by far the most important as a cause of disease, and in them the sewer-gas merely conveys the specific germs, which have got into it more or less accidentally, and which are not necessarily present in sewer-gas.

In the case of those diseases which are known to be caused by bacteria it is not difficult to understand that the bacteria entering the drain, and finding there food, moisture, warmth, and other requisites for growth, should propagate rapidly, and subsequently getting into the air of a house through a leak in the drain, might enter the body of some person, and might cause the diseases of which they are the etiological agents. Many cases have been reported which tend to prove more or less conclusively that typhoid fever, pneumonia, diphtheria, cholera, dysentery, cerebro-spinal meningitis, ery-

[1] Rigby: Parke's Hygiene, vol. 1, p. 148.

[2] It is true that there is often an escape of sewer-gas into a house without any sickness resulting from it, but it is to be remembered that not every one exposed to a contagion, or other cause of disease, contracts the disease. In this connection the investigations of Lassaer, Viertelj sch. f. öff. Gesundth. Pflege. 1881, 13, p. 341) are of interest, who found that in six out of ten houses in which there was an escape of sewer-gas there occurred one or more cases of disease which could be attributed to the sewer-gas, while in the other four houses there was no such disease; and that such diseases occurred in only sixteen per cent. of a considerable number of houses in regard to whose sanitary condition he was ignorant, as against the sixty per cent. in the houses in which here was known to be an escape of sewer-gas.

stipelas, and scarlet fever, can be caused by sewer-gas into [illegible]

But in addition to these diseases which are caused by a well-known specific germ, there are many other forms of disease (most of which are probably also of bacterial origin) which are generally regarded as being due to sewer-gas poisoning, and which, unfortunately, are sometimes classed under that much abused term "malaria," taken in its etymological and broadest sense, "bad air." Although in a general way numerous allusions have been made to this class of diseases, both in medical and in general literature, yet when one comes to study the subject, it is surprising how little the nature of the individual diseases of this class have been studied, and how impossible it is to say just what diseases can and cannot result from sewer-gas poisoning, and what group of symptoms in any case would lead one to suspect sewer-gas poisoning. During the past few years I have seen a number of cases of this class, which I would like to present to this Association. The time allowed for the reading of papers prevents my giving more than a brief summary of each case, and indeed the cases are so few in number, and some of them are so imperfectly studied that I cannot hope to offer any well-grounded conclusions, but only to bring up points for discussion, and to suggest the importance of an exhaustive study of the subject to those members who are better able than I to investigate it. It is certainly important to know to just what disease inmates of a house in which there is an escape of sewer gas are exposed, and this study is undertaken not with the idea of discovering the essential cause of any disease, but only to replace the general statements found in medical literature in regard to the diseases which may be caused by that very complex body, sewer-gas, by statements a little more definite, and to lay a foundation for future work on this subject. For convenience of study I have grouped the cases not according to the houses in which they occurred, but according to the symptoms which they presented.

The most generally recognized effect of sewer-gas poisoning is a disturbance in the functions of the alimentary canal, and, as illustrative cases of this group, I would report the following:

Case I.—Mr. E., æt. fifty-five, slept in a small room, with untrapped stationary wash-stand, and for ventilation opened a window on a small well in the centre of the house, in which well an untrapped gutter-pipe connecting directly with the sewer opened not three feet from the window. On pouring oil of peppermint into a distant part of the house-drain, the odor of peppermint filled this bedroom immediately. For five or six years, almost as long as he had lived in this house, Mr. E. vomited every morning as soon as he got out of bed, and presented no other symptom. The pipes were trapped, and the plumbing put in proper order, and the vomiting of Mr. E. stopped immediately; so that, in this case, the vomiting, and the vomiting only, seemed to be directly caused by the sewer-gas. The wife of Mr. E., who slept in this same room, died of sewer-gas poisoning (Case XVI.), and his son-in-law, who did not sleep in this same room, but whose room was ventilated by the same window in the little well, also presented symptoms of sewer-gas poisoning (Case XIX.).

Case II.—Mr. G., æt. forty-three, had been working very assiduously during two weeks in January, in a building in which the plumbing was full of defects; among other defects, sewer-gas had free access to the hot air which warmed the building. During the last week of his work in this building, and for a week afterward, Mr. G. had a severe diarrhœa, or rather purging, which came on every morning, and consisted of half a dozen or more copious watery discharges which exhausted him greatly, and then ceased, not to return till the same hour next morning. The diarrhœa finally yielded to quinia.

In these two cases the purging and vomiting occurred separately, and were not combined as they are usually, and as they were in the following cases:

Case III.—Mr. T., æt. twenty-eight. In the spring the drain under the kitchen was broken, and the contaminated earth was upturned in order to repair the break. Mr. T. went down to look at the work, and was attacked with vomiting, purging, loss of appetite, and great prostration, which lasted about a week, and ran its course without fever. The prostration lasted about two weeks.

Case IV.—Mr. H., æt. thirty-two. In the spring the drain under the basement was broken, and the contaminated earth was upturned in order to repair the break. Mr. H. examined the work several times, and before it was completed he was attacked by vomiting, loss of appetite, and violent purging, the stools being copious, watery, and of dark color. The purging continued about a week, and ran its course without fever. The prostration lasted about two weeks.

A Mr. P., who had charge of the repairs of this same drain, was attacked by a severe sore throat.[1]

[1] Cases somewhat similar to these first four, in which nausea, vomiting, purging, and prostration, were prominent symptoms, have been described by Foss (Medical Examiner, 1879, i, p. 47; Sixth Amer. Pub. Health Ass. Rep., 1879, p. 362), Eaton (Sani-

Enlenberg, in his book *Die Lehre von den Giftigen Gasen*, states that the symptoms of chronic poisoning by sewer-gas are nausea, vomiting, colic, weakness, and diarrhœa, or constipation.

Workmen engaged in cleaning out sewers which have become choked are often overcome by the very foul gases occurring in such sewers, and present a very acute and severe form of sewer-gas poisoning.

Such cases have been reported by Harbordt (*Berl. klin. Wochenschr.*, 1871, p. 289), Seifert and Macintosh (*Phil. Med. Bull.*, 1883, v. p. 148), and many others. These patients are usually in a condition of collapse, comatose, and have general convulsions; if recovery takes place, there usually remains for a considerable length of time a condition of physical and mental weakness. Enlenberg (loc. cit.) divides these cases into three classes: *First*, a mild form, of which the symptoms are nausea, vomiting, colic, weight in epigastrium, pressure on vertex, dyspnœa, rapid, and small pulse, great weakness, and, in some cases, delirium. *Second*, a condition of clonic and tonic spasm, together with faintness and unconsciousness. *Third*, a severe form, in which the patients become slowly or rapidly asphyxiated. Face is pale, lips cyanotic, breathing and pulse faint. As this condition of asphyxia passes off, convulsions appear. The unconsciousness may continue three or four days, and when it passes off the patient vomits and complains of pain in his head and limbs. There is a disgusting stink emitted from the body of such patients. Dr. Herbert Barker (*Malaria and Miasmata*, 1863) has approached this subject from an experimental standpoint. He found that dogs kept in a box which was supplied with air from a cesspool vomited and purged, and would not eat. They recovered rapidly when removed from the sewer-gas. After a short exposure to the gas there was only slight exhaustion, but after a long exposure there was fever, and a condition of feebleness lasting six weeks. Dogs exposed in the same way to hydrogen sulphide fell insensible, had rapid respiration and pulse, and violent heart-action, tremors, and convulsions. Unless the percentage of hydrogen sulphide in the air was very small, the dogs died; and, in any case, they only recovered slowly from the effects of their exposure to it.

In these four cases the sewer-gas poisoning caused only a temporary gastro-intestinal disturbance which was accompanied and followed by a prostration of short duration, but in the following case the subsequent prostration continued a long time.

CASE V.—Mr. P., æt. eighteen, was present when a very foul privy vault, which had been unused and covered up for many years, was opened. He was immediately seized with faintness, and with severe vomiting and purging. Afterward he was extremely prostrated, and for five or six years he was an invalid, unfit for any physical or mental effort. He was very weak, and appeared to be in a condition of general debility without presenting any evidence of organic disease.

tary Record, 1865–66, p. 525), C. Handfield Jones (Med. Times and Gazette, July, 1871, p. 9, 2d case), Finklenburg (Vierljsch. f. gerichtl. Med., 1874, N. F., 20, p. 301), Trend (Brit. Med. Journ., November, 1878, p. 719), and Morrill (Bost. Med. and Surg. Journ., December, 1884, p. 531).

The following case is interesting in many respects.

CASE VI.—Miss S., æt. forty. An iron ventilating pipe of light weight ran up in the wall of her bedroom from the drain to the roof. The joints of this pipe were found, on examination, to be open, and the peppermint test gave a strong odor of peppermint in the room. Miss S. had occupied this room less than a year when she had an attack of acute Bright's disease, œdema of lungs, and general œdema, vomiting, diarrhœa, etc., abundance of casts, and a large amount of albumen in the urine. She was taken to the hospital, and made a good recovery. After a few months she returned to this same room, and during the next ten years had no return of the Bright's disease, but suffered from frequent attacks of complete loss of appetite, great prostration and wretchedness, vomiting, diarrhœa, coated tongue, and headache. On several of these occasions the urine was examined, and was found to be free from albumen and casts. Each attack lasted from one to three weeks, and she had eight or nine such attacks each year. A year ago she had three severe attacks of facial erysipelas; she was scarcely over one attack a fortnight before she had another, and it was these attacks of erysipelas which led to an examination of the plumbing. The defective pipe was replaced by a thicker one properly leaded, and Miss S. has enjoyed good health ever since.

In this case the escaping sewer-gas caused a succession of attacks of gastro-intestinal catarrh during ten years, at the end of which time the specific micrococcus of erysipelas probably got into this particular drain, and escaping into the room caused the succession of attacks of erysipelas, and both these kinds of attacks promptly ceased when the leak in the pipe was stopped. The question naturally arises, whether the attack of acute Bright's disease with which this series of diseases commenced, was not also the result of sewer-gas poisoning. The following cases, it seems to me, make it extremely probable that this is so.

CASES VII. and VIII.—Dr. P., æt. sixty-five. Connected with the bedroom in which he and his wife sleep, is a little room in which there is a water-closet, which they never use in the winter time and only rarely in the summer; so that the closet is rarely flushed, and it is certain that the trap often dries out. The soil pipe of the water-closet runs to an hermetically sealed cesspool. At times a bad odor is noticed about this closet. In the early part of the winter his wife was attacked by a low form of fever, which was followed by an attack of acute Bright's disease (general œdema, albumen and casts in the urine) from which she completely recovered. During his wife's illness Dr. P. began to complain of general weakness, numbness of extremities, dyspnœa, palpitation, insomnia, pain in the occiput, failing eyesight, and confusion of mind. These symptoms have continued up to the present time. Micturition is frequent. Urine is abundant and contains a small amount of albumen and many finely granular casts of small calibre. Otherwise physical examination is negative except for a high arterial tension.

The occurrence of Bright's disease almost simultaneously in the wife and husband, makes it probable that there is some local cause for the disease, and taken in connection with the case of Miss S., renders it very probable that this local cause is sewer-gas, and this probability is strengthened by the seven cases which follow.

CASES IX. and X.—Mr. K., æt. sixty-eight. Connected with his bedroom was a bath-room, the plumbing

of which was in very bad condition, allowing a free escape of sewer-gas; and under the basement floor the house-drain was broken and a large pool of sewage had gradually formed, into which a workman, who unsuspectingly walked over it, sank to his knees. Mr. K. came to the office on May 8th, complaining of great weakness, dyspnœa on exertion, and looked haggard and miserable. At that time his urine contained no albumen. He grew rapidly worse, and the next night his dyspnœa became orthopnœa, he had complete anorexia, he developed general œdema and œdema of the lungs, and his urine became scanty and contained a large quantity of albumen together with hyaline and granular casts. On May 17th he became delirious, then comatose, and died on May 20th, twelve days after he first came to the office for medical advice. His wife soon afterward began to present the same symptoms: dyspnœa, prostration, haggard face, etc. It was then suspected that the plumbing was in bad order, and an examination revealed the condition of things described above. Mrs. K. was removed to a room entirely unconnected with the plumbing, and made a rapid and complete recovery.

Case XI.—Mrs. G., æt. fifty-six. In March she had an attack of indigestion, at which time her urine was examined and found to contain no albumen. On the following May she moved into another house, and after that time she did not feel well, and about the middle of July an attack of acute Bright's disease was ushered in by a chill, vomiting, and diarrhœa. The urine contained one eighth per cent. of albumen and numerous hyaline and finely granular casts of small calibre. During the first few days of her sickness she had numerous chills and a low form of fever, the temperature not rising above 101°; and during the whole sickness she was extremely prostrated, so that she could not raise herself up in bed; she also had absolute anorexia and a profuse diarrhœa. An examination of the house revealed numerous leaks in the soil pipes, one hole being two inches square, through which there was a free escape of sewer-gas. The plumbing was repaired, and as soon as it was possible, Mrs. G. was removed to another house. The albumen had disappeared from the urine by the end of July, and on August 20th she was able to walk out on the street, although she did not recover her strength for several months.

Case XII.—Mr. C., æt. sixty, as a contractor worked for a long time at a very foul sewer. Before he had finished working at it he was seized with weakness, dyspnœa, and œdema, and an examination of his urine showed one-sixth per cent. of albumen, and numerous hyaline and granular casts. He continued to present the symptoms of chronic Bright's disease, and died after a sickness of less than a year, from uræmic poisoning.

Case XIII.—Mr. H., æt. seventy-five. About a year and a half ago he moved his office, where he worked more than ten hours a day, to a room which was heated by hot air, which was contaminated by sewer-gas, so that when the room was shut up for a few days the air became extremely offensive. At the time of moving into this office Mr. H. was an unusually vigorous man for his age. A month or two later he began to be troubled by diarrhœa and frequent micturition. To these symptoms were added dyspnœa, palpitation, sweating, frontal headache, and failing eyesight. The dyspnœa then became orthopnœa and œdema of the legs appeared. The pulse was quick, irregular, and intermittent. The heart's action was violent and irregular; the area of cardiac dulness was increased, but no murmurs could be heard. The urine contained one-eighth per cent. of albumen, and a few hyaline casts. Mr. H. is still living. He has ascites and much œdema, and a very irregular and labored action of the heart.

Case XIV.—Mr. X., æt. fifty-five, went to work in an office in which there was a stationary washstand, the soil-pipe of which was untrapped and allowed a free escape of sewer-gas. The previous occupant of this office died, and his death certificate reads fatty degeneration of the heart, although he was said to have had Bright's disease also. Mr. X. soon after commencing work in this office began to be troubled by dyspnœa on exertion, headache, and general weakness. The dyspnœa and weakness became extreme, and about a year after commencing work in this office he was suddenly seized with a right-sided hemiplegia, followed in a few hours by coma of short duration. At that time the urine was examined and found to contain one-sixth per cent. of albumen, and hyaline and finely granular casts. The pulse was irregular and intermittent; the heart's action violent and labored; area of cardiac dulness was increased; no murmurs; arterial tension high. He left his office and travelled about and improved slowly and steadily. His urine was last examined six months ago, at which time it still contained albumen and casts. His heart's action continued labored and he was feeble. Since that time he has continued to improve in strength.

Case XV.—Mr. S., æt. fifty. In the cellar of his store, in which he spent most of his time, there was a large opening into the drain. In the middle of the winter he began to be troubled by dyspnœa and general weakness. Pulse was rapid and feeble; heart's action extremely labored; urine contained a large amount of albumen (¼ per cent.) and hyaline and finely granular casts. He developed ascites and general œdema, and a secondary pleuritis and pericarditis, and finally died from exhaustion.

The last ten cases make it very probable that one of the effects of chronic sewer-gas poisoning is some form of nephritis. In the absence of autopsies, the nature of the renal lesion cannot be determined. In all the cases there were diarrhœa and extreme prostration. In almost all of the cases the quantity of albumen in the urine was rather small, and in the case of Mr. K. (Case IX.), when he first presented the symptoms of dyspnœa and prostration, albumen was absent from the urine and did not appear till several days later;[1] so that it seems in these cases as though the symptoms can hardly be altogether explained by the nephritis, but rather that the change in the kidneys is only one manifestation of a general infection of the body by the poison of the sewer-gas.

In the last three cases there wa a very labored action of the heart; a greater degree of cardiac disturbance even than is usually met with in Bright's disease; so that it is a question whether the poison of sewer-gas does not cause a degeneration of the heart's substance as well as of that of the kidney.[2] That this is not improbable, appears from the following case, in which, in addition to the general prostration, the heart seems to have been especially

[1] In this connection compare the first case reported by C. Handfield Jones (Medical Times and Gazette, July, 1871, p. 9).

[2] I have seen a number of cases, each one of which is too imperfect to report, but which taken collectively, lead me to believe that there is a form of disease, rather difficult of exact diagnosis, which presents the symptoms of prostration, emaciation, anæmia, anorexia, œdema, dyspnœa, and diarrhœa, and the physical signs of a weak heart, often, but not always, associated with a small amount of albumen and sometimes with casts in the urine, and occasionally with œdema of the lungs, and which is due to sewer-gas poisoning. Recovery usually takes place in these cases when the patient is removed from the sewer-gas infection.

involved, although there is no evidence of any renal lesion.

Case XVI.—Mrs. E., æt. forty-eight. The very unsanitary condition of her bed-room (which was not discovered till just before her death) was described in reporting the case of her husband (Case I.) who for years vomited every morning. Mrs. E., who had previously been a strong, healthy woman, occupied this room for seven years, during the whole of which time she felt weak, miserable, and nervous. Her principal symptoms during these years were great weakness and nervousness, loss of appetite, dyspnœa, palpitation, and vomiting, (occasionally there was bloody vomitus at the time of menstruation, but only when menstruation was imperfect). She grew steadily weaker, so that during the last month of her life she could scarcely walk across the room, and her stomach was so irritable that she vomited almost all her food. She was anæmic and fleshy, but her flesh was soft and flabby. Pulse was small, 110. Heart's action irregular and labored. Great enlargement of the liver and of the spleen, apparently the result of passive congestion. Her urine was examined several times, and was found to contain neither albumen nor casts. Her pulse became more and more rapid; being 120 a fortnight before she died, and during the last week of her life was too rapid and irregular to be counted. Toward the end of her illness she had several attacks of precordial pain, and on the last day of her life she had two severe attacks of angina pectoris, which were relieved by hot applications and inhalations of nitrite of amyl. Soon after the last attack she became comatose and died in a few hours. No autopsy was allowed.

A common effect of sewer-gas poisoning is a condition of general weakness, and I am inclined to think that some cases of nervous prostration are due to this cause.[1] Indeed, weakness, irritability, loss of appetite, dull headache, and drowsiness are a group of symptoms which play a principal part in almost every form of disease due to sewer-gas poisoning; but there are some cases, such as the following, in which these symptoms are alone present and constitute the entire disease.[2]

Case XVII.—Mrs. K., æt. fifty-five. The cold air box of the furnace in her house was connected indirectly with the drain. For several years she has suffered in the winter time from loss of appetite, diarrhœa, vertigo, drowsiness, and great prostration. She was tired out on slight exertion, was greatly depressed, and every duty seemed a mountain in her path. She continued to grow weaker until she could scarcely walk. Her temperature was normal. Pulse 110. The urine was free from albumen. Although scarcely able to be out of bed she was sent south and improved rapidly. In her absence the house was put in good sanitary condition, and after her return she continued to improve, and is now well.

XVIII.—Mrs. V., æt. sixty. The plumbing in her house was old, and was in very bad condition; there being a number of leaks in the soil pipes. During the winter she has frequently had attacks of chilliness. In April she began to feel very weak and miserable, had no appetite, complained of dull headache and of great drowsiness, she was much depressed and did not feel able to accomplish anything. At the same time that Mrs. V. suffered in this way her daughter became feverish and had a typical attack of typhoid fever. A servant in the house had a succession of sore throats and headaches during the whole winter. Mrs. V. went away from her house while it was being repaired and gradually regained her health and strength.

Case XIX.—Mr. T., æt. twenty-six, lived for a short time in the house, the unsanitary condition of which was described under Case I. During the whole time that he was living in this house he felt weak and wretched, had a dull headache, no appetite, and was drowsy. He recovered very soon after leaving the house.

In all of these cases of general weakness the patients have complained of great drowsiness, and this, in my experience, is one of the first and most constant symptoms of sewer-gas poisoning. In the following case it was the only symptom.

Case XX.—Mrs. F., æt. sixty, in consequence of anxiety and worry got into a condition of great nervous exhaustion, and was greatly troubled by insomnia. In the midst of this condition she moved into a house, the plumbing of which was found to be in a very defective condition, allowing the escape of sewer gas in all parts. As soon as this was discovered she was taken to another house, but during the five days that she remained in the house with defective plumbing, her obstinate insomnia disappeared and she slept not only during the night but also during most of the day. When she left this house, however, her insomnia returned.

Chronic sewer-gas poisoning often manifests itself in an irregular low form of fever either with or without chills, as is seen in the following cases.[1]

Case XXI.—Mr. M., æt. sixty-seven, had locomotor ataxia for several years and had been pretty closely confined to his sitting-room and bed-room, both of which were on the same floor, and between them with doors always wide open, was an old-fashioned pan closet, which was found by the peppermint test to leak badly, and on examination the cement was found to have fallen away from the joint of the soil pipe leaving a large opening. Mr. M. was suddenly seized with a severe chill followed by fever and by a delirious semi-comatose state. During the next week he had frequent chills followed by high fever and sweating. He was frequently comatose during and after the chills, and was much of the time delirious. The chills occurred once or twice a day at no regular hour, usually in the morning, and occasionally in the afternoon also. The leak in the water closet was then discovered. It was found impossible to remove him effectually from the sewer-gas infection, but he was moved into a hall bed-room and the water closet door was kept shut, with the result, that he had one slight chill on the day that he was moved but no more, and the temperature fell to 99½° the next day and was afterward normal. He continued to have absolute anorexia, grew steadily weaker and finally died from exhaustion.

Case XXII.—Dr. H., æt. thirty-one. On February 7th he did not feel well and had no appetite, and in the evening his temperature was 102°. He did not feel well during the next week, but his temperature continued normal till the evening of February 13th, when it was again 102°. He then began to be troubled by a severe dry cough, his appetite continued poor, but his

[1] Compare Morrill (Boston Med. and Surg. Journ., Dec. 1884, p. 531).

[2] Compare Eaton (Sanitary Record, 1885-6, p. 595) and Cosgrave (Trans. Acad. Med. Ireland, 1885, p. 365, Case 101).

[1] Compare Burrall (N. Y. Hosp. Gazette, 1879, p. 662), Nourse (Sanitary Record, October, 1880, p. 127), Trask (N. Y. Medical Record, October 16, 1875), and Noel (Am. Health Ass. Reports, 1876, p. 362).

temperature continued normal till the evening of February 19th (another interval of just six days), when it was 103°. After that time the temperature continued elevated; being a little above normal in the morning and rising to 102° or 103° in the evening. On February 21st he discovered a very bad break in the drain beneath the kitchen floor; the ceiling of the kitchen was broken and above it was his bedroom with a poor floor, thus allowing the foul air an easy access to his bedroom. The break in the drain was repaired as soon as possible. On the 24th, 25th, and 26th he had slight epistaxis, bowels were rather constipated, the dry troublesome cough continued. On February 27th the temperature was A.M. 99°, P.M. 104°. On the 28th A.M. 101°, P.M. 100¾°. On March 1st, A.M. 99½°, P.M. 99½°. After this the temperature remained normal, his appetite slowly returned, and he gradually recovered the flesh which he had lost.

Such cases of fever have been frequently reported. The epistaxis and the dry troublesome cough recall typhoid fever.

CASE XXIII.—Mr. P., æt. thirty-four. In an alcove off from his bedroom is a stationary washstand, in which there was a leak, and consequent escape of sewer-gas. He was attacked by pain in his head and back, loss of appetite, and great prostration. He had a low form of fever for two weeks, the temperature being 101 every night with great regularity, and between 99½° and 100 each morning. After two weeks of this low form of fever, the temperature commenced to rise, and the spleen commenced to enlarge, although it was not so before. At the same time diarrhœa commenced, and there were tenderness and gurgling in the right iliac fossa; a couple of days later he had an epistaxis, and about a week later rose spots appeared. In other words, after a low form of fever continuing for two weeks, an attack of typhoid fever commenced with all the typical symptoms, which then appeared for the first time. The typhoid fever ran a perfectly regular course, and lasted three weeks. In this case, then, the sewer-gas poisoning produced a low form of fever, during the course of which the system became infected with the typhoid fever germ, probably also from the sewer-gas.

Under Cases IV. and XVIII. sore throats have been mentioned as occurring in houses at the same time with other forms of disease due to sewer-gas poisoning, and cases of sore throat have often been reported as being due to sewer-gas poisoning.[1] In many of these cases the sore throat has a diphtheritic character, as in the following case:

CASE XXIV.—Mrs. C., æt. sixty, lives in a house in which, within two months, there have been a case of pneumonia, a case of erysipelas, and a case of measles in the adult. Beneath the basement floor there is a bad break in the drain. One evening the stench from this drain was very offensive, and Mrs. C., who was sitting in the basement, was seized with a chill, headache, and sore throat. That night she was feverish, and the next morning there was a compact, oval patch of white membrane on each tonsil, measuring about a half by a quarter of an inch in its long and short diameters respectively. In thirty-six hours these patches fell off, leaving quite deep ulcers, which slowly healed. There was no enlargement of the cervical glands. The throat was sore, and deglutition was painful. Pulse varied from 80 to 90. Temperature was 100½° in the morning and 102° in the evening. On the fourth day of the disease the fever left her, and she felt in every way so much better that, although still very weak, she considered the disease as over, as indeed it was, although she continued greatly prostrated for several weeks.

Such cases as these may be considered either as mild forms of diphtheria, which they probably are, or they may be considered as necrotic tonsillitis, following the classification in *Strümpell's Text-book of Medicine*.

Not infrequently sewer-gas poisoning shows itself in disease of the nervous system. The most common of these diseases thus produced is neuralgia, as can be seen from the following cases[1]:

CASE XXV.—Mrs. L., æt. thirty, slept in a middle room opening out of a bath-room. An examination of the plumbing showed that it was very old, and leaked in almost all parts, the bath-room being particularly defective. During five or six weeks she suffered from intense neuralgic pains, which commenced in the lumbar region and extended around into the groin and down the posterior and other outer surfaces of the thighs and legs. These pains recurred daily, and were so intense as not only to require morphia hypodermatically, but they reduced the patient to a very low and precarious condition. She was also extremely weak, and had no appetite. When the trouble with the drain was discovered, she was moved to another house. After she was taken to the other house there was no return of the pain, her appetite returned, and she quickly regained her strength. There could hardly be a more striking example of neuralgia due to sewer-gas poisoning than this one.

CASE XXVI.—Mrs. T., æt. thirty-two, lives in a house in which the plumbing was found to be in an extremely defective condition. In the latter part of December she had an attack of fever, lasting three days, the evening temperature being 103.8° on one night and 103° on another. Even after the fever left her she continued to be weak, and to have no appetite. On the first of January she was attacked with severe neuralgia of the ninth right intercostal nerve, which continued till the third week of January, when she went out of town. Early in February she returned to her house, and on the second day the pain returned, and was accompanied by a slight attack of jaundice. She then moved into another house, and in a couple of days her neuralgia ceased, and in a week the jaundice disappeared also.[2]

There is another form of nervous disease which I am inclined to think may also be caused by sewer-gas, and that is myelitis of the anterior horns, which is probably an infectious disease.

CASE XXVII.—Mr. B., æt. twenty-nine, worked in a little wooden shed built on the very edge of the Albany Basin, and just over the outlet of one of the principal city sewers. The stench at times was so bad that the clerks had to relieve each other frequently, and go up the street for a little fresh air. He worked in this place, from May till October, for three summers. During the third summer he noticed that he was very drowsy during the day, although somewhat restless at night, and that his appetite was very bad. On the first of September,

[1] Compare Carden (Brit. Med. Journ., March, 1884, p. 600), Davis (Sanitary Record, March, 1883, p. 401), Brown (Brit. Med. Journ., March, 1876, p. 340), Morrill (Boston Med. and Surg. Journ., December, 1884, p. 531), and Nourse (Sanitary Record, October, 1880, p. 127).

[1] Compare Morrill (Boston Med. and Surg. Journ., December, 1884, p. 531).

[2] Jaundice has been noticed in cases of sewer-gas poisoning, by C. Handfield Jones (Med. Times and Gazette, July, 1879, p. 9) and by Burrall (N. Y. Hosp. Gazette, 1879, 7, p. 662).

1880, at 5 P.M., his legs suddenly gave way under him, and he fell. He managed to walk home, and to creep upstairs on his hands and knees. The next day he could move his arms and legs a little, but inside of three days he lost completely all power of voluntary movement, except that he could masticate his food pretty well; for a short time he was unable to close his eyes. There was no disturbance of sensibility, but a complete loss of all the reflexes: superficial, deep, and organic. He went through a typical attack of myelitis of the anterior horns, with great muscular atrophy, and the electrical reaction of degeneration. At the end of a year he could get about on crutches, and in about two years and a half he could walk without a cane. Even at the present time, seven years after his attack, he is emaciated and weak.

Case XXVIII.—Mr. B., æt. forty-two, was obliged to inspect for several weeks a sewer which was being repaired, and which emitted a very bad stench. In the course of this inspection he was attacked by a chill followed by fever, and during three weeks he had a low continued fever, with frequent chills. After the fever ceased he did not regain his health, but during the next year steadily lost flesh and strength, his appetite became poor, he had neuralgic pains in various parts of the body, and his health failed in every way. His urine was free from albumen and casts. At the end of a year his legs suddenly gave way under him, and he fell several times in the street. He then developed a well-marked case of myelitis of the anterior horns, from which, after several years, he made a complete recovery, and is now in good health.

Finally, I will report a case in which the diagnosis as to the nature of the disease is doubtful, but which seems to be an undoubted case of sewer-gas poisoning.

Case XXIX.—J. L., æt. six and a half, slept in a middle bedroom, with connecting bath-room, in a house in which there was a free escape of sewer-gas, especially in this bath-room. The sanitary condition of the house was described under the case of his mother (Case XXV.), who presented a well-marked case of severe neuralgia, due to sewer-gas poisoning. His grandmother, who had lived in the same house, suffered from great prostration and an obstinate bronchitis,[1] both of which quickly disappeared when she moved to another house. I saw the boy in consultation once only. He had, for a week or more, such a severe frontal headache, probably of a neuralgic character, as to suggest the possibility of cerebral disease; but no other cerebral symptoms could then be discovered. His tongue was coated, pulse was rapid, there was decided enlargement of the spleen, and his urine contained albumen. During the first two weeks of his sickness he had a fever ranging from 99° in the morning to between 100° and 101° in the evening. He became extremely emaciated. About a week before his death there was, during several days, a partial suppression of urine. Cheyne-Stokes respiration appeared, he gradually sank, and, without any expression of pain on his face, he died, a little less than three weeks after the commencement of his sickness. No autopsy was allowed.

In all of these twenty-nine cases there was an escape of a large amount of sewer-gas into the air which the patient breathed, and at the time that each case was observed it seemed extremely probable that the sewer-gas was the cause of the disease. I have notes of a number of other cases of this class, but as they are not in all respects convincing, I have not reported them; and I would only say that it seems to me that phthisis, and also diabetes mellitus, may sometimes have their origin in sewer-gas poisoning.[1]

From a consideration of these twenty-nine cases, we may conclude that it is probable that the following conditions may result from sewer-gas poisoning:

1st. Vomiting and purging, either separately or combined.

2d. A form of nephritis.

3d. General debility, in some cases of which the heart is especially involved.

4th. Fever, which is frequently accompanied by chills.

5th. Sore throat, which is frequently of a diphtheritic character.

6th. Neuralgia.

7th. Perhaps, also, myelitis of the anterior horns.

These conditions may occur separately, but are frequently combined, and it is especially common for the fever to be associated with the other forms of sewer-gas poisoning.

Finally, in cases of sewer-gas poisoning there is one group of symptoms which is almost always prominent, and these symptoms are: loss of appetite, drowsiness, extreme prostration, and a dull, unpleasant feeling in the head; and whenever this group of symptoms occurs, not as the result of an attack of acute disease, but as a chronic condition, we are justified in suspecting that the patient is exposed to sewer-gas infection.

If we summarize the cases of sewer-gas poisoning which are scattered through medical literature, and which have been mentioned in the notes to this paper, we find that more or less satisfactory evidence has been adduced that the following diseases may result from sewer-gas poisoning:

8th. Zymotic diseases, such as: typhoid fever, pneumonia, diphtheria, cholera, dysentery, cerebro-spinal meningitis, erysipelas, and scarlet fever (in these cases undoubtedly the sewer-gas merely acts as a vehicle for the specific germ).

9th. A condition of asphyxia, which, in its severe form, is characterized by coma, convulsions, and collapse.

10th. Puerperal fever.

11th. Abscesses.

12th. Lymphadenitis.

13th. Acute aural catarrh (?).

[1] In regard to bronchitis due to sewer-gas poisoning, compare Nourse (Sanitary Record, October, 1880, p. 127), and Ward (Sanitary Record, 1880–81, N. S., 2, p. 411).

[1] In addition to the numerous reported cases of disease due to sewer-gas poisoning mentioned in the notes to this paper, there are some other forms of disease which it is claimed are due to sewer-gas poisoning. Thus, Playfair (Lancet, February, 1887, p. 251), Cosgrave (Trans. Acad. Med. Ireland, 1885, 3, p. 365), Brown (Brit. Med. Journ., March, 1879, p. 346), and Trask (N. Y. Med. Record, October 16, 1875), think that puerperal fever may be due to this cause; while Brown (loc. cit.), Owen (Lancet, 1878, 2, p. 172), Cheadle (Lancet, August 17, 1878), and Noel (Am. Pub. Health Ass. Rep., 1876, p. 362), think that abscesses and enlarged and suppurating lymphatic glands may be due to sewer-gas poisoning; and Cassells (Edinburgh Med. Journ., 1878, 18, p. 910) thinks that acute aural catarrh may be due to the same cause.

SOME CLINICAL OBSERVATIONS ON THE EFFECTS OF THE LATEST FEBRIFUGE, ACETPHENETIDINE.

BY THOMAS J. MAYS, M.D.,
PROFESSOR (ADJUNCT) OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC

THE latest febrifuge has been brought to the notice of the profession in the *Centralblatt für die medicinische Wissenschaften* of February 26, 1887, by Messrs. O. Hinsberg and A. Kast, under the name of acetphenetidine.

According to the *Pharmaceutical Record* (May 1, 1887), they obtained it from carbolic acid by the process of nitriting, separation of the arthro- and para-nitrophenols, acetylating the latter, reducing the *p*-nitrophenol to *p*-amedophenol, which is called phenetidin, and acetylating the phenetidin with glacial acetic acid, making the final product, acetphenetidine. It crystallizes in colorless needles, is slightly soluble in water, but dissolves in alcohol, and in glacial acetic acid. It is tasteless, and melts at 135° Celsius.

Their experiments on dogs with this agent showed that it was only in very large doses—from 45 to 75 grains—that it produced toxic symptoms. These consisted in accelerated respiration, somnolency, giddiness, vomiting, and cyanosis; and after having fully convinced themselves of its harmlessness in doses of from 15 to 30 grains per day, they essayed to test its action on fever in the human body. They gave it in the pyrexia of phthisis pulmonalis, in doses of from 45 grains to 2 drachms, three times a day, and found that it gradually lowered the temperature without producing any untoward effects whatever. Its action is said not to be accompanied by any sudden dissipation of heat, or by any profuse hydrosis.

Shortly after the announcement of these results appeared, I had the pleasure of receiving a small amount of the drug through the kindness of Mr. Merck, with which I made a few observations in its relation to the fever temperature of pulmonary phthisis. The agent yielded some good results, but on account of the limited amount at my command, the test extended only over a few days, a period too short to arrive at any definite conclusion concerning the utility of the drug. The first was an acute case of phthisis, with an afternoon temperature of 105½° Fahrenheit, which was preceded by a chill. I gave her three grains of acetphenetidine every three hours. She had another chill the next day, and her afternoon temperature was 104°. The third day her temperature had sunk to 101° P.M., and she had no chill that day. The fourth day she had another chill, but her temperature only rose to 101½° P.M. The fifth day her temperature was down to 98°. Discontinued the acetphenetidine. On the sixth day she had no chill, but her temperature rose to 101° P.M. On the seventh day she had a chill, and her temperature rose to 103⅘° P.M. Began the acetphenetidine again. Ninth day, temperature 100⅘° P.M. Tenth day, 100⅗° P.M. At this point the supply became exhausted, but from even this limited experience with the drug it was quite obvious that it had a marked influence in depressing the temperature. Besides this, her cough, appetite, and general condition seemed to mend.

The other was an old cavity case, with a temperature of 102° Fahrenheit P.M. He was given the same dose. Temperature, second day, 101⅖°. Third and fourth days, same. Fifth day, 100° P.M. This patient's expectoration and cough also seemed to improve while he was taking the medicine.

It is slower in its action than antipyrine or antifebrine, but probably on the whole safer. In order to obtain its best effects I think it should be given in a large dose at the outset, and then followed up with further doses in accordance with the demand of the supervening symptoms. It is worthy of investigation, and I shall give it a further trial in the near future.

THE PROGNOSIS OF CERTAIN HEART MURMURS,

WITH SPECIAL REFERENCE TO THE SELECTION OF RISKS FOR LIFE INSURANCE.[1]

BY FRANK DONALDSON, JR., B.A., M.D.,
OF BALTIMORE, MD.

THE great importance of the prognosis in any given case of cardiac disease is, I venture to assert, not sufficiently emphasized by the average practitioner. There has always been a strong tendency to overestimate the importance of heart murmurs in themselves (heart disease in general), and to take too grave and sombre a view of them, without considering their position, or the symptoms associated or not associated with them. Of late years, however, especially among those skilled in auscultation, there has been a decided change of opinion, and the hopelessness which was once attached to the presence of organic disease of the heart no longer obtains. The discovery of a murmur is not now regarded as an infallible indication of unavoidable and early death. We now recognize the numerous forms of disease to which this organ is subject; we discriminate one affection from another, and we distinguish between what are conditions of passing debility and anæmia, and those graver ones of dilatation, valvulitis, and fatty degeneration.

Indeed, it may not be too broad a statement, that since the introduction of that most wonderful heart drug, *strophanthus*, even these severer forms of disease have much less terror for the physician, and that with this agent for good in our possession, the chances of a favorable prognosis are a hundred fold increased.

Again, this shifting of opinion as to the fatality of cardiac murmurs is beginning to work an important change in the selection of risks for life insurance in this country, as it has already done in England, where valvular disease, as such, is no longer a cause for total rejection, and where increasing attention is given to the signs of dilatation and displacement of the heart and to deficiency in the general circulation; the really risky cases are excluded,

[1] Address delivered before the State Medical Society of West Virginia, July 14, 1887.

and the persons selected for insurance who seem to have as good a prospect of prolonged life as those who are passed as "good" or "fair" risks—in other words, the risks are graded—such cases being insured at a higher premium.

As an examiner for a number of large companies I have given the subject considerable attention, *and it has been my practice for at least two years, in cases where there was a systolic basic murmur (aortic or pulmonary), or a slight mitral murmur, with no history of rheumatism, gout, or syphilis, and with no secondary symptoms, to postpone the risk.* I have, as I say, followed this rule in a number of cases, and have had the satisfaction of seeing the murmur disappear and the person get his insurance, of which it would have been so unjust to deprive him and his family. I am fully aware that the position I am taking will be criticised by the more conservative medical directors and examiners; but this is a question which undoubtedly needs to be brought forcibly before the medical profession, and especially before examiners of life companies. The majority of medical examiners, I am inclined to believe, rarely *locate* the murmur in any given case, and more rarely consider its significance — whether there may not be good grounds for postponement of the risk. Only the other day, in talking to a medical examiner of many years' standing, and an exceptional diagnostician, he said, "Well, really, this is something I never considered in all these years; if I heard a murmur in any situation I turned the risk down, and that ended it." I could not but tell him he had in that case done many people grave injustice.

This by way of introduction. I desire first to give brief consideration to the latest views as to the prognosis of certain organic murmurs, and, secondly, to the significance of the so-called functional murmurs, their situation and causation.

I. Prognosis of Organic Murmurs.

The elements of prognosis in heart disease are complex, but not necessarily complicated. To prognosticate the course and issue of any given case we must find—

1. The valve affected, and the relative danger attaching to the particular lesion.

2. The actual condition of the orifice and valve, and the degree of obstruction or amount of regurgitation to which the lesion has given rise.

3. The nature and tendency of the morbid change in the valve, whether stationary or progressive.

4. The condition of the muscular tissue of the heart, and how far compensatory changes may be counted on.

5. The mode of life of the patient.[1]

The relative frequency of the different forms of valvular disease of the heart is mitral regurgitation, aortic constriction; aortic regurgitation, mitral constriction; tricuspid regurgitation, pulmonary constriction; pulmonary regurgitation, tricuspid constriction.

In this paper I shall not consider diseases of the right heart. In order of relative danger diseases of the left heart may be placed in the following order: Mitral stenosis, aortic regurgitation; mitral regurgitation, aortic stenosis; though the latter is the most fatal when it is developed late in life, when it is progressive in character, and when compensatory hypertrophy is with difficulty established.

The actual condition of the orifice or valve is next to be ascertained, in which our chief guide is the murmur; but it must be remembered that a loud murmur may be produced by very slight change, while a scarcely audible murmur may be indicative of extensive destruction. A loud murmur is, on the whole, of less serious import than one which is weak and soft. The former is indicative of the force of the heart, at least. A long murmur, except in cases of mitral or aortic stenosis, is usually indicative of early and comparatively slight disease and of efficient action of the heart. A short murmur, on the other hand, says Broadbent, is sometimes significant of impending danger. The roughness or smoothness of a murmur *may be* of diagnostic significance. An accent at the beginning of a murmur shows that the valves still act as a check to the influx of blood. A post-systolic or diastolic murmur means that the valves come together accurately at first, but not afterward.

The pulse may be a source of considerable information. In aortic obstruction it is long, and the initial wave slight. In aortic regurgitation we find, of course, the typical "Corrigan's pulse." In mitral stenosis the pulse is small, but regular; in mitral regurgitation (when considerable) the pulse is small and very irregular.[1]

Hypertrophy and dilatation are too often looked upon as caused by the valvular disease *alone*, and as a measure of its extent. While this is to a great extent true, no direct ratio constantly holds between the amount of hypertrophy and of valvular obstruction, which would seem to show that there is something beyond the mechanical which contributes its quota of causation.

The connection between the valvular disease and hypertrophy or dilatation is dependent upon several considerations:

1. Different affections of the valves have greater or less tendency to the production of structural alterations.

2. The time of life at which the lesion takes place is of great importance.

A valvular lesion established in youth, for instance, will probably, by reason of the great hypertrophy give little trouble for many years at least.

After middle age, on the other hand, it would prove fatal before hypertrophy could be accomplished.

Again, the mode of life of the person will greatly influence the development of hypertrophy. Moreover, valvular disease accompanied by structural change in the heart is of more serious import than when not accompanied by it. For instance, in aortic constriction there must either be increase in

[1] Broadbent.

[1] Probably due to the increase of blood pressure in the auricle. See Foster's Journal of Physiology, vol. iii., 1882: "The effect of variations of intracardiac pressure upon the vagus nerve." H. Sewall and F. Donaldson, Jr.

the propulsive power of the heart or *diminished arterial tension*. Increased power, however, can be gained only by hypertrophy, and a direct aortic murmur accompanied by hypertrophy is of more serious import than one not accompanied by it.

In aortic insufficiency a certain amount of blood returns to the ventricle at each systole. To compensate for this the capacity of the ventricle must be enlarged; which is exactly what happens in this lesion. Dilatation, then, in such a case is totally distinct from that following structural weakness of the heart walls. For in the former case hypertrophy takes place and prolongs life; in the latter, no such saving process is brought about.

Another important factor influencing prognosis in heart disease is the *stationary* or *progressive* character of the lesion. For instance, congenital malformation of the valves would be stationary, and valvular lesions from acute endocarditis are also for the most part stationary, except when the inflammatory process has caused a mitral stenosis. Disease from chronic endocarditis and degenerative changes in later life, and due to gout and renal disease, is, on the other hand, progressive.

Again, dilatation of the orifice may derange the functional efficiency of a valve which itself has undergone no alteration. This is common with the mitral valve, and may occur at any time of life, induced by acute disease or by debilitating influences such as anæmia, chlorosis, etc.

The distinction, says Dr. Broadbent, which it is usually most important to make is between the lesions originating in acute endocarditis, which are probably secondary, and the lesions produced by chronic inflammatory or degenerative changes, which are inevitably progressive.

So much for the prognostic significance furnished by the heart itself. The other chief conditions which influence the future of a case of heart disease are:

Age. Valvular disease appears to be more serious in early childhood than a few years later; the weakened heart cannot keep pace with the active growth at this age.

Sex. It is somewhat remarkable that mitral stenosis is more common in women than men. In 53 cases seen by Broadbent, 38 were females, 15 males. Personally, I have never seen a case in man. Aortic insufficiency, however, is more frequent in man. Girls with valvular disease are more likely to break down at puberty than boys.

The mode of life of the patient, and the tension of the arteries, have a considerable bearing upon prognosis in any given case.

Such being the prognostic indications in heart disease generally, let us consider the prognosis in—

1. *Aortic Stenosis.* The supposed frequency of aortic stenosis is chiefly due to the fact that all those cases in which a systolic aortic murmur is heard are classed as cases of true stenosis, when in reality in only a small proportion of such cases does this condition actually exist. The various conditions under which an aortic systolic murmur may exist will be considered later. In a given case, however, where we have an obstruction to the flow of the blood we find considerable hypertrophy; and if this be due to the narrowed valves, the aortic second sound will be indistinct. If, however, the sound is accentuated, the hypertrophy is due to renal disease, and tends to a less favorable prognosis. The pulse in true aortic stenosis will be long and slow, and the artery will be small and full between beats.

Aortic stenosis proves fatal by the slow operation of dropsy, mitral regurgitation following as a result of dilatation. But the danger is not imminent so long as the aortic obstruction is uncomplicated by mitral trouble. Dropsy having once set in in a case of aortic stenosis, there is less probability of recovery than in most other valvular affections. Finally, most authors agree in placing aortic stenosis as the least dangerous of valvular troubles.

II. Aortic Regurgitation.

The diagnosis of this affection offers no difficulty. The elements of prognosis, when the symptoms have not become prominent, and compensation is fairly effectual, are briefly as follows: If with the diastolic murmur the second sound be distinctly audible in the neck, the dilatation and hypertrophy are inconsiderable, and the pulse exhibits the collapsing character only in a moderate degree. If the valvular lesion be the effect of acute endocarditis, and therefore probably stationary, the prognosis is favorable. If, on the other hand, the second sound is completely abolished, with hypertrophy, dilatation, and a collapsing pulse, the prognosis is grave, and the comfort and life of the patient depend greatly upon his family constitution, age, habits, occupation, and circumstances. It should be remembered that the heart's nutrition is not well maintained after middle age, and that there is a tendency to increased peripheral resistance with increasing age.

Coming on late in life, aortic regurgitation is always serious. The disease is progressive, and finally ends either from a failure of the ventricle in systole (in which case we have the attacks of angina, paroxysmal dyspnœa, weak and very irregular pulse, etc., but no dropsy), or death ensues from venous obstruction, and the symptoms do not differ materially from those of mitral insufficiency. Sudden death may be expected, and is the rule in aortic insufficiency.

III. Mitral Insufficiency.

Mitral insufficiency is not a deadly kind of valvular affection, and is probably less serious than aortic stenosis, which is placed lowest in the scale of danger. A circumscribed mitral murmur, not heard in the back, is of little import; but care must be taken not to take the soft murmur of a gaping orifice and a weak heart as an indication of slight mischief.

The first indication of marked insufficiency is the accentuation of the pulmonary second sound, followed by hypertrophy and dilatation of the right ventricle from increased pulmonary pressure, with displacement of the apex of the heart, and hypertrophy of the left ventricle, with consequent increased cardiac impulse. At this stage the symptoms may become very serious and alarming, but proper treatment and care may establish the equilibrium

and the patient continue in fairly good health for years.

Moreover, a very important element in mitral insufficiency is the hypertrophy of the right ventricle and the consequent increase in its force, by which it causes increase of pressure in the left auricle, which resists the back flow of blood, while the pressure in the left auricle must be greater than the pressure in the arterial system. Much depends upon the extent of this peripheral resistance; the less the arterial tension the more favorable the prognosis. And it is just in this we may find, I think, the reason why in so many cases digitalis fails to do any good, the patient becoming steadily worse under its administration. Digitalis, while increasing the power of the heart, also increases very considerably arterial tension, which is the very thing in certain cases we wish to avoid. As long as compensation is established our prognosis is very favorable, but it grows, of course, less so if there are signs of dilatation, vascular derangement, etc.

So much for the prognosis, speaking generally, in these various cases of heart disease. How should the knowledge thus obtained affect our present way of dealing with risks for life insurance?

There is no questioning the fact that valvular disease may exist for many years without producing any secondary or disagreeable symptoms. Dr. Symes Thompson says that "it might cause surprise to some to learn that during ten years about 1000 cases came under the notice of a single physician in which chronic valvular disease existed, the presence of which was not indicated by symptoms, and did not sensibly interfere with the health."

Again, of 684 persons tabulated (by Sir Andrew Clarke), 326 sought medical advice, not for heart disease, but for disorders of digestion; 134 for disorders of the nervous system; 61 for rheumatic affections; 47 for respiratory disorders; 30 for skin diseases, and 33 for gout. In none of these cases was the presence of valvular disease indicated by symptoms, nor was the heart to any extent affected.

Dr. Thompson gives the following data from his own experience in two large life insurance companies, where risks with heart murmurs are "rated up":

"Taking the experience of one of my own offices (the Equity and Law Life), I find from the last analysis of invalid lives that of 5 cases rated up for disease of the mitral valve the average age of the insurers was 35 years, the average addition 23 years, and no deaths occurred during the period comprised in the report; whilst out of 15 cases in which the nature of the heart disease is not specified the age was 41, average addition 8 years, and 3 deaths occurred. From the subsequent course of these cases it appears that of the first series, those with mitral disease, two have since died, one after having been insured for 13 years, to whose actual age 7 years had been added. Had 12 been added, no loss would have occurred to the office. In the other fatal case, which also occurred from heart disease, 10 years had been added to the actual age, but the policyholder died at the end of five years, and an addition of 20 years would have been needed to save the office from serious loss.

"In two other cases of the mitral series the results have been good; the cases were rated up to 20 and 25 years respectively, and are now living, having been insured, the one for 22 and the other for 12 years. Taking this series alone, the gains fairly balance the losses.

"In the other class, that in which no definite valvular disease was mentioned, 6 deaths have occurred, one by accident one year after the policy was taken out, and two others at short periods, viz. 6 years and 9 years. In two they lived 27 and 18 years respectively.

"Of the 7 cases now living, all have lived long enough to cover loss, and 3 have proved very advantageous. Thus, this class, like the first, has not been found by experience unsatisfactory, although in many of the cases the extra rating had not been nearly sufficient; and, curiously enough, this is specially true with the lives that have proved unfortunate.

"The general results of the experience of these cases have been confirmatory of the received opinion that where definite heart disease exists, a really considerable addition is demanded."

In view of these facts, the injunction of the various American companies that "heart disease shall be cause for absolute rejection," seems to me to be too absolute and too general, while I recognize fully the importance of a wise caution in the selection of lives for insurance, it seems to me that too great caution has hitherto been observed. After all, in examinations for life insurance, justice should be done the applicant as well as the company. But the question naturally presents itself: How shall we in such cases distinguish the favorable from the unfavorable risk?

The first important point to be determined is whether there is any evidence of degenerative change, obstruction of the circulation, or liability to rheumatism or gout. The mechanical and vital power of the heart is more important than the murmur, and, within certain limits, than the seat and nature of the valve lesion. The only two forms of such disease which I consider as "ratable" are mitral insufficiency and slight aortic stenosis. Speaking generally, aortic defect is most to be dreaded; mitral lesions, on the other hand, being the most hopeful.

Again, a heart that has been damaged by rheumatic fever during the period of growth is more likely to be adjusted to the extra work thrown upon it than when the disease occurred in adult life. Often all evidence of disease disappears in a few years, and the heart beats in the normal position, showing that no serious hypertrophy has occurred.

The most marked and easily recognized lesions are not those to be most dreaded; there is more importance to be attached to signs of weakness or enlargement of the heart, to a change from its normal position, to signs of degeneration in its walls or those of the bloodvessels, and to the conditions of life, than to the murmur merely; and a patient whose life is happy, active, pleasant, and prosperous, will be more likely to live out his expectancy than one who, with a smaller amount of actual lesion, has an harassed, anxious, life of toil, confinement, and trouble. Sir A. Clarke himself lays down five propositions with regard to disease of the mitral valves: First. That there shall be no degeneration of the heart. Secondly. That the disease shall have existed two years. Third. That the ventricles shall be in good order. Fourth. That the arteries shall be sound. Fifth. That there is no persistent basic

nor recurrent hepatic congestion; that colds shall not hang about the patient, and that his general health shall be good; given all these and, says Sir Andrew, "the mitral disease will not shorten life." Dr. Bristowe says: "When I find a mitral systolic murmur extending over many years, that the second sound is not accentuated, and that the apex (of the heart) is in its place, I think I am justified in admitting them" (for insurance).

Dr. Clifford Allbutt made a very practical suggestion on this point. It was that such cases should be put upon the early-payment system, so that all premiums should be paid up before the age of thirty-five.

Finally, Dr. Borland says:

"The whole summary of the matter seems to be that the selection and admission of these cases is one of great delicacy, and requires the highest qualifications of experience and tape, sound judgment on the part of the physician; that though in the hands of a few men of exceptional experience a few (very few) cases of aortic valvular disease may be admitted at a greatly advanced premium rate, yet that as a general rule for the majority of examiners the safe course will be rejection. But as to mitral disease of some standing, dating from early life, and occurring in otherwise healthy, temperate persons, subject to no laborious exertion or great anxieties, and having no enlargement or displacement of the organ, and no fatty or other degeneration of heart or arteries, an addition varying with circumstances from ten to twenty-five years should be made to the actual age."

FUNCTIONAL MURMURS, THEIR SITE, CAUSATION, AND PROGNOSTIC IMPORTANCE. HOW SHOULD THEY AFFECT THE SELECTION OF RISKS FOR LIFE INSURANCE?

The heart murmurs known as functional have been the subject of much discussion and difference of opinion. It has been customary, however, to include under this term all those cases in which the murmur depends upon temporary and curable conditions, or in which no distinct alteration of the valvular segments can be detected after death. Functional murmurs are invariably systolic in time, and are heard, as the case may be, over the true pulmonary area, close to the left of the sternum between the second and third ribs; 2d, over a space of about an inch and a half to the left of the sternum, and in the second interspace just where the left auricle comes up from behind to the left of the pulmonary artery; 3d, over the aorta. The murmurs in these three situations are usually found in some form of chlorosis or anæmia, or in the course of acute febrile disease, and may be dependent upon a changed condition of the blood, constriction or dilatation of the artery, or acute dilatation of the heart.

Pulmonary systolic murmurs are more frequent than any other form of cardiac murmurs. Dr. Guiteras, of Charleston, states that in 100 consecutive cases he found 62 systolic pulmonary murmurs.

The clearness of the murmur depends upon the proximity of the artery, the thinness of the chest walls, and the proximity of the main trunk to the capillary circulation. It seems to be generally acknowledged that a systolic pulmonary murmur may be *developed in healthy individuals* by modifying the act of breathing; and this is a point which is of special interest and importance with reference to life insurance. These murmurs are confined in ordinary breathing to the expiratory act, being loudest at the beginning. They frequently disappear when the chest is elevated in inspiration. Sometimes a very slight, shallow inspiration causes the murmur to disappear. Again, it does not disappear even upon the deepest inspiration. Another interesting and important peculiarity of this murmur is that it is very frequently inaudible when the individual is in the erect position, but at once appears when the recumbent posture is assumed. Again, the murmur is sometimes only heard with the first beat that occurs with expiration. Finally, the fact that a loud systolic murmur in the pulmonary region may be found in a perfectly normal heart cannot be too forcibly emphasized. The causation of these inorganic pulmonary murmurs has been a source of much discussion.

It has been generally asserted that the sudden propulsion of a large amount of spanæmic blood into a dilated vessel would be sufficient cause for their production. Again, Dr. Russell holds that the murmur is caused by a constriction of the pulmonary artery by a dilated left auricle, while Quincke, of Berlin, thinks that the artery is compressed by the heart during its systole, following an uncovering of the base of the heart by a retraction of the lung, which, I take it, is the opinion of Balfour.

Dr. Guitéras would explain a murmur in the pulmonary area as a "dynamic obstructive murmur produced by the effect of changes of blood pressure upon the semilunar valve. A certain degree of pressure in the artery must tend to prevent the opening of the valve; this would or might cause a slanting position of the valve and a narrowing of the orifice, with the production of a sonorous whirl"—an explanation, I think, which has much to support it, for an accentuated second sound always accompanies a pulmonary murmur—sure evidence of increased pressure in the pulmonary artery. Dr. Guitéras goes on to say that, "the fact that such murmurs are not more frequently developed at the aortic orifice is due to the greater power of the left ventricle and the wider distribution of the systemic circulation."

Pulmonary murmurs then, as we have seen, are found under very varying conditions, and are *compatible with perfect health*. Are we then justified in rejecting a person for life insurance in whom after careful examination, we diagnosticate such a functional murmur? I say emphatically, No. Only two weeks ago I examined one of the most thoroughly healthy men I have seen for a long time—a man of fine physique, good habits, excellent family history, an active and prosperous business man. His pulse was 76, full and strong, but on listening to his heart I discovered a distinct murmur over the pulmonary artery. I was, much to my own chagrin and his annoyance, compelled by the company to turn the risk down. Surely great injustice was done, and I hold that such cases are perfectly legitimate risks for a life insurance company to take.

AORTIC SYSTOLIC MURMURS.

Functional murmurs at the aortic orifice are found in anæmia, and in the course of acute febrile diseases such as typhoid and rheumatic fevers, and also in those persons who are under great strain, who are overworked, anxious, and excited. There are many causes which may produce an aortic systolic murmur. If in an examination for life insurance such a murmur is found, the important point to be ascertained is whether the murmur indicates the existence of actual obstruction. If there be marked anæmia, other things being equal, we should, of course, conclude that the murmur was hæmic. It should be remembered that a systolic aortic murmur appearing at middle age or in advanced life will seldom be due to actual narrowing of the orifice, but is probably due to roughness and irregularity of the valves or slight dilatation of the aorta. The loudness or general character of the murmur does not give us much help. Hæmic aortic murmurs are usually soft and smooth, but so also may be murmurs due to extreme narrowing, especially when there is weakness of the ventricle. Thus a gradual enfeeblement and disappearance of a systolic aortic murmur may be a most serious prognostic fact. It is plain, then, that there are many things to be considered and careful attention required before we can say whether a systolic aortic murmur is surely functional. But such a conclusion having been arrived at, it is only just to the person who is an applicant for life insurance to postpone the risk in order to see if the murmur may disappear. I have made it a rule for some time past to postpone such risks, and have no reason to regret such action. We have been too sweeping in the past in condemning such cases, and so depriving men who are in reality perfectly healthy, of the protection of life insurance.

Much might also be said on that condition known as curable mitral regurgitation, but my paper has already exceeded all reasonable limits, and I shall have accomplished my purpose if perchance I have shown that a murmur by itself is nothing; that they have little if any pathological significance, unless other changes are associated with them; if I shall have impressed the fact that great care is necessary for a proper prognosis, in justice to our patients and ourselves; and, finally, if I shall have forced upon the notice of medical examiners how necessary it is to decide exactly the significance of any given murmur before rejecting the person applying for the insurance.

510 Park Av., Baltimore

SYPHILITIC CIRRHOSIS OF THE LIVER IN A CHILD.

By J. OLIVER JENKINS, M.D.,
OF NEWPORT, KY.

The occurrence of syphilitic cirrhosis of the liver in a young child is but seldom met with in general practice, and the report of a case may not be without interest.

Katie, aged twelve years, when first seen was bright and intelligent. Her parents gave a satisfactory history of entire freedom from specific disease. Thorough inquiry failed to elicit the slightest evidence of any hereditary or other disorder. The mother aborted at about the fifth month of her first, second, and fifth pregnancies, but from causes satisfactorily explained. The father and mother enjoy good health. The children of the family are healthy and robust, presenting no symptoms of scrofula, syphilis, or other disease; their teeth are even, regular, well shaped, and firm.

Katie, the second oldest of the children, we are informed, was a fat, rosy baby, and was never troubled with any sickness until about the third year, at which time she and an older brother were vaccinated by a barber. Two attempts resulted in failure; the third produced a small pustule at the point of puncture on the arm, and was speedily followed by the development of an intractable ulcer on the posterior surface of the right knee. Her brother had a similar ulcer on the sternum.

So-called smallpox occurred in both the children three or four months afterward, but did not present certain characteristics of the disease. The eruption was confined chiefly to the face and thoracic regions, was pustular in form, and distributed unevenly over the surfaces, and very few crusts were formed. There were no cicatrices or pits left, except where the initial ulcers, previously spoken of, had been located. Both children were but slightly ill, and promptly recovered. The boy has remained well, except during an attack of typhoid fever in 1883; the girl, however, was afflicted with various sicknesses for a period of four years after the vaccination. In the order named came: first, at three years, smallpox; fourth year, scarlatina; fifth year, diphtheria; sixth year, pneumonia of right lung followed by dropsy. The diphtheria was of great severity, and was complicated with "sore eyes" and greatly enlarged submaxillary glands, the latter suppurating and requiring the use of the knife. Her recovery was very protracted.

When about seven years of age her parents noticed that her gastric and hepatic regions were becoming prominent, but paid little heed to the circumstance. The distention becoming greater from year to year, medical advice was sought, and she came under notice in May, 1885, when twelve years of age, and was seen occasionally from then until March, 1887. Her abdomen was found to be greatly enlarged in all directions; the umbilicus depressed; the superficial veins not prominent; her body fairly well nourished; the skin clear; no jaundice or œdema. Palpation showed the liver to be enlarged in both lobes; also the spleen. Dulness exceeded normal limits two inches downward in the hepatic, and a fraction over three inches in the splenic regions; sulci could be determined between the right and left lobes of the liver, and between the left lobe and the spleen. A tympanitic space was found at the cardiac orifice of the stomach and in the lower abdomen. The prominence of the latter was due to the crowding downward of the intestines by the mass above. Her appetite and digestion were good; there was absence of pain; slept well; temperature normal; lungs and heart normal.

Measurements made at this date and the two succeeding years were as follows:

	Inches.		
	1885.	1886.	1887.
Circumference of body at lower end of xiphoid cartilage	25	26	28
Midway between above point and umbilicus	27	27½	28¾
At umbilicus	27	27	28¼
From end of xiphoid cartilage to genital fissure	14	15	16½

These measurements indicate the rate of enlargement to have been about one inch annually.

Notwithstanding the great pressure which was exerted upon other organs, the absence of distressing symptoms

continued until a few hours previous to death. This very immunity to complications made a diagnosis impossible. The urine was frequently examined, and was always found to be normal.

In seeking a diagnosis the presence of a deep-seated echinococcus cyst was taken into consideration, because her diet had consisted largely of raw scraped beef during her several illnesses. A small quantity of albuminous fluid was secured from the most prominent part of the liver, and microscopically examined by Dr. E. B. Bayliss, but gave only negative results. Shortly afterward a diagnosis of hepatic cancer was made at the clinic of one of the medical colleges in Cincinnati.

The treatment during the entire time from 1885 until her death, in 1887, consisted of systemic tonics, preparations of mercury, arsenic, and potassium iodide, alternated as was deemed advisable. Later events proved this to be the appropriate treatment, although probably not begun at a date sufficiently early to eradicate the diseased nodules found after death.

The last forty-eight hours of life were marked by hemorrhages from both stomach and bowels. The left side of the neck and face became swollen and œdematous, and left hemicrania appeared, otherwise there was no discomfort. One hemorrhage greater than the preceding ones suddenly terminated life.

Autopsy, twenty hours after death, by Dr. James M. French, of Cincinnati. Rigor mortis moderate. Slight ecchymotic discoloration of posterior surface of the body. Eyelids œdematous, especially the left, the swelling involving the whole of that side of the face. Brain not examined. Heart and lungs normal.

The liver appeared as a mass of round or rounded nodules of a yellow color, varying in size from a hen's egg to a pea, and even smaller. The organ was with difficulty dissected from its abnormally firm attachments and removed. It was considerably enlarged, weighing five pounds, irregularly nodulated throughout, and much firmer than usual; in no way, in fact, resembling a healthy liver. Section revealed numerous firm, irregularly distributed fibrous bands, and a large number of rather firm, not hard, masses, varying in size between a hulled walnut and a split pea. These masses were found in greatest number in the region of the transverse fissure. The surfaces of these on section was not altogether smooth, but emitted no juice, and none could be obtained by scraping.

The gall-bladder was partially filled with bile and mucus. The spleen was about twice its normal size, but not much firmer than usual. The right kidney was normal in size and appearance, but on incision two small collections of pus were found. The left was much increased in size; capsule slightly adherent; interstitial tissue hyperæmic; and the pelvis contained about one drachm of pus. The stomach and intestines contained dark fluid and tarry blood. A few slightly enlarged mesenteric glands were observed, but no general adenopathy.

Sections of the liver for microscopical examination were made mostly in such a manner as to include a portion of the harder nodules referred to above, and some of the surrounding tissues. These nodules were found to be composed almost entirely of very delicately fibrillated connective tissue, exceedingly rich in nuclei, the fibres of which had been divided in the section both longitudinally and transversely. Some embryonic cells were also present. The appearance was that of old gummatous formations. The tissue surrounding these masses was made up of the parenchymatous elements of the liver, for the most part in a state of fatty degeneration, and a large amount of fibrous tissue. The bands of this tissue were more than double in amount those which normally separate the hepatic lobules, and, in addition to being very irregularly distributed, contained exceedingly numerous embryonic cells. These fibrous bands were largest in the portions of the organ corresponding to the great depressions of its surface.

That other causes than alcoholism will operate to produce a cirrhotic condition of the liver is becoming more and more manifest. Syphilis as a cause of the disease has been acknowledged since the description of it given by Gubler, in 1852. French, in the *Reference Handbook of the Medical Sciences*, vol. iv., p. 543, states: "In a certain small proportion of cases the disease is independent of alcoholic indulgence. Acquired syphilis may produce a hyperplasia of the interstitial tissues of the liver which is usually very irregularly disseminated throughout the organ." As gummata were found numerously scattered throughout the liver, and were proved by the microscope to be syphilitic in character, the conclusion that the cirrhosis was dependent upon acquired syphilis must be accepted.

As to the method of infection, the supposed vaccination is the only acceptable source. Bumstead, Taylor, and others point out the dangers and accidents which may result from the careless use of an infected scarifier of whatever kind. Also, that the blood of a syphilitic, introduced into a wound on a non-infected person, will produce the original disease. In the present case it is not improbable that the barber, in vaccinating the children, used an implement common to his trade, a razor, which had been improperly cleansed after use; or he may have used crust virus, in which there was a portion of unhealthy blood. From whichever cause happening, the thought of danger should be a warning to the physician to have his instruments scrupulously cleansed after each and every vaccination, and, if possible, not to use humanized virus in the operation.

MEDICAL PROGRESS.

THE CREASOTE TREATMENT OF TUBERCULOSIS.—SOMMERBRODT is quoted by the *Medical Chronicle* for July, 1887, as follows:

The author gives the results of his treatment of about 5000 cases of tuberculosis of the lungs and larynx, continued throughout nine years. For two years—1878 to 1880—he used Bouchard's solution of creasote. Since 1880 he also used gelatine capsules, containing each ¼ of a grain of creasote and 3 minims of balsam of tolu, commencing with one capsule the first day, and gradually increasing to six capsules a day in the fourth week, and after two months nine per diem; as many as from 600 to 2000 capsules being thus taken by each patient without a break. He did not neglect other means, such as "lung gymnastics" and ventilation, and other favorable conditions, but still continued the creasote treatment throughout. The result in many cases was a very favorable influence upon the disease—a marked diminution in the cough, even at the commencement of the treatment, lessening of expectoration, improvement of the appetite; even night sweats and fever ceased without the use of quinine, agaricin, etc. The physical signs were often greatly improved, even to the disappearance of dulness on percussion. He believes that he has thus *cured* cases of tuberculosis by insisting upon a continuance of the treatment. Tubercle of the larynx,

though a hindrance, is not a bar to its use. It is at least a testimony to its value that after nine years' experience the author steadily pursues this treatment. The following case is given: "On November 17, 1886, a gymnasium student, aged sixteen, came under my notice with considerable tubercular infiltration of the right lung. He had taken the usual dose of one capsule of creasote three times a day, but on December 28th he came again and reported very considerable improvement in every respect. Through a misunderstanding it appeared that he had taken three capsules at a time, three times a day—about half a gramme per diem. His excellent state of health induced me to make no alteration, and on January 16, 1887, he had used in this way 627 capsules, in 73 days 7¾ drachms of creasote. He hardly coughed at all, had increased 6 pounds in body weight, there was no dulness at the right apex, only slight rhonchus, expectoration had quite ceased, the urine was normal, and his general health had so much improved that he went back to school."

A Convenient Application for Rhinitis, with Ozæna.—Penny, in an article in the *British Medico-Chirurgical Journal*, No. 16, 1887, gives the following as having done good service in his hands:

Iodoform	gr. x.
Ol. eucalyptol.	ʒj.
Pulv. acid. boracic.	ʒj.
Ol. sassafras ethereal	ɱx.
Vaseline	ad. ʒj.

Excision of the Knee-joint by Longitudinal Incision.—Dr. Senn thus describes this operation as performed by Riedinger, of Heidelberg:

The patient was a boy about six years of age, suffering from tuberculosis of the knee-joint. Evidently the disease was in its earlier stages, as the joint was only moderately swollen and did not present that sense of semi-fluctuation as is the case in advanced fungous inflammation of this joint, at the same time the articular surfaces were not displaced. The operation was performed as follows: The whole limb was thoroughly washed with warm water and soap and subsequently with a 1:1000 solution of sublimate. Esmarch's constrictor was applied about the upper third of the thigh, and a *longitudinal* incision made over the centres of the patella, dividing the tissues with one stroke down to the bone, and passing through the lower portion of the quadriceps and the tendon of the patella. At a corresponding point the patella was sawn through in the same direction, so that the divided patella and the soft parts presented two symmetrical halves, which when separated exposed the joint fully to inspection, both by sight and touch. Without much difficulty the lateral halves were so widely separated that the lower end of the femur was brought fully into the wound and the articular end was removed with a saw, the line of section being below the epiphyseal cartilage. The tibial end was treated in the same manner. At least two osseous foci were exposed by the bone sections, and each was carefully scraped out with a sharp Volkmann's spoon. This long anterior incision fully exposes the upper recesses of the synovial sac, and renders the extirpation of the entire capsule an easy matter. After the extirpation of the capsule with curved scissors the whole surface was irrigated with a sublimate solution and carefully dried, and the parts restored to their normal relationship, and the two halves of the patella tacked together by applying two catgut sutures passed through the tendinous covering and periosteum, but not through the bone.

The only provision for drainage was a rubber drain introduced into the upper angle of the wound. As the limb is kept in a nearly perpendicular position for at least twenty-four hours, the drain occupies the most dependent position of the wound, and answers all requirements. The remainder of the wound is closed with silk sutures. A copious gauze dressing, embracing nearly the entire limb, is applied, over which a thick layer of absorbent cotton and equable compression by bandaging limb from toes to groin. A posterior hollow splint, with footboard, serves to immobilize the limb. The constrictor is not removed until the whole dressing is applied. The first dressing is not changed for a week, when the drain is usually found outside of the wound. As the wound at this time is usually firmly united, the sutures are removed and the limb put in a plaster-of-Paris splint. Anatomically this operation presents a number of advantages. I have always observed after making the transverse incision, that on account of muscular traction of the extensors of the leg, there is not only a tendency for separation of the fragments of the patella, but a constant traction always results in the formation of a wide and often ugly cicatrix, in the skin; conditions which are avoided by the anterior longitudinal incision. When the articular ends of the bones are brought fully into such a wound by forcibly flexing the leg upon the thigh, the entire synovial sac is brought into full view and rendered accessible to removal with scissors. The tissues divided in the direction of the axis of the limb, serve a most useful purpose in securing immobilization during the process of repair.—*Journal of the American Medical Association*, July 16, 1887.

A Formula for Ergot, Hypodermatically.—Hildebrandt recommends the following:

Aqueous extract of ergot . . .	3 parts.
Glycerine,	
Distilled water, each	7 parts.

From five to twenty drops may be injected beneath the integument of the thigh or abdomen to check uterine hemorrhage.—*Journal de Médecine*, July 3, 1887.

A New Test for Milk.—A new test for water—that is, pump water—in milk has recently been proposed by Herr Szilasi. This depends on the fact that sulphate of diphenylamine is colored blue by the action of an exceedingly dilute solution of a nitrate. As well water always contains more or less nitrate, its presence in milk can be detected. The test is carried out thus: Twenty minims of sulphate of diphenylamine is placed in a small porcelain vessel and a few drops of the milk which is to be examined added to it. If this contains even five per cent. of average well water, a blue tinge will gradually distinctly appear. Sulphate of diphenylamine is easily procurable, and only costs about sixpence an ounce, so the test may be readily tried.—*Lancet*, June 11, 1887.

THE PROPER METHOD OF EXAMINING THE BREAST.—DR. GROSS says that, to examine properly a woman's breast, she should be lying on her back. If examined in any other position, it can be so manipulated as to convert it into any tumor. When on her back, examine by pressing the tips of fingers back through the breast against the chest walls, and not by pinching the structures up between the fingers—*College and Clinical Record*, July 1, 1887.

THE TREATMENT OF ACUTE CORYZA.—FRITSCHE, of Berlin, has found the following useful:

R.—Acid. acetic. glacial,
Acid. carbolic. . . . . aa gr. 30
Mixt. oleoso-balsam. . . . ʒ 2
Tr. moschi . . . . . ♏ 15.—M.

Fifty drops of this may be put upon cotton and enclosed in a convenient flask. Inhalations, at first every half hour, and later at longer intervals for ten minutes, will be found beneficial.—*Berliner klinische Wochenschrift*, July 4, 1887.

THIERSCH'S METHOD OF SKIN-GRAFTING.—DR. MYNTER reports this method, as proposed by Thiersch, of Leipzig, and as he has used it in the Buffalo (N. Y.) General Hospital, as follows:

The granulations are removed by the aid of a sharp spoon down to the underlying firmer tissues, and the rather copious bleeding stopped by pressure with compresses dipped in a solution of chloride of sodium, 0.6 per cent. The bleeding stops generally in the course of five to ten minutes. The flaps are now cut with a sharp razor, generally from the outer surface of the humerus, and then transferred directly on the shining surface of the wound, deprived of its granulations. The flaps are five to ten centimetres long, one to two centimetres broad, and contain, even if microscopically thin, the whole papillary layer and a part of the underlying stroma.

The flaps are completely unravelled by aid of two probes, and then firmly pressed against the surface by aid of a soft sponge dipped in the same solution of chloride of sodium. The transplanted wound is covered with a piece of protective dipped in the salt solution and an antiseptic bandage applied over it, which is not disturbed for eight days; the superficial wounds produced by the razor healing in eight days under iodoform bandages. If the wound be completely covered with flaps it will be healed in about eight days; but in very large ulcerations, especially after severe burns, it is almost impossible to get skin enough from the patient himself, and one will then after eight days have the opportunity of seeing not only the growth of the flaps themselves, but also the stimulating effect on the border of the wound, which is quite wonderful to observe. It is astonishing to see how quickly the cicatrization progresses in those large ulcerations from the border and the numerous islands formed by the new flaps.—*Buffalo Medical Press*, July, 1887.

THE TREATMENT OF NERVOUS DYSPEPSIA.—IHRING, of Offenbach, is quoted as follows by the *Journal of Dietetics*, No. 2:

We should first recommend a milk diet—lukewarm milk with or without crushed rusk. Unfortunately, through the habit of using highly seasoned dishes from youth up, we often find an aversion to milk. To cover its taste with sweet is not to the purpose, but we have at times added a small quantity of malt extract. The addition of cognac to the milk, as is used with phthisical patients, is equally imprudent. The best thing to give it an agreeable taste is a little table salt. Among other things we may add a little cocoa, deprived of oil, but with little sweetening, and some interruption, as in many cases an aversion for cocoa sets in. Tea is in some cases tolerated when cocoa causes loathing, but coffee has a dyspeptic effect. Tea has a tendency, especially if strong, to produce nervous palpitation of the heart, and, if left too long on the leaves, dyspepsia. If none of these beverages can be taken, we may at first use soup for breakfast. Amylaceous substances here especially find their place, and in the preparation of such among these as barley, oats, rice, etc., the precaution to have them long and thoroughly boiled should be given. For a second breakfast, some bouillon free from fat, with an egg; at noon, a plate of soup, with a corresponding portion of extract of meat. The last meal of the day ought to be taken at least two hours before going to bed, and should consist of beef-tea, with eggs and stale white bread. Milk may at any time be taken in place of one of these meals; so may eggs beaten with a little salt and water.

According to physiological experiments on digestion, boiled albumen appears to be more easily and rapidly digested, but in reality raw albumen is more easily peptonized than the solidly cooked lumps of albumen, because the movements of the stomach separate it with facility, and it is soon saturated with gastric juice.

If the appetite gradually returns, and the articles of food named are tolerated in larger quantities, we may intercalate another meal; the soup may also be prepared from scraped beef and the latter eaten with it. Gradually a saucerful of the articles already mentioned may be taken every two or three hours. This amount will be sufficient for a long time.

If, under this regimen, gastric digestion takes a normal and rapid course, the sense of hunger may be felt oftener than every two or three hours, but the patient should not yield to his cravings. The time will then soon arrive when more consistent food can be taken, especially properly cooked meat. The opinion that so-called white meat is especially well borne, has not always been confirmed in practice. It may perhaps be the case with pigeon and chicken, etc., but veal is certainly barely tolerated, owing, probably, to the large amount of gelatine it contains. As a rule, boiled meat is better tolerated than roast; and cold roast better than warm, and this is particularly true of game. With the latter, fat gravy, and the fat of pork especially, plays a very injurious part. Meat not too strongly salted is well borne, but the smoking process will spoil this advantage. The flesh of geese and ducks is difficult to digest.

Most patients will dislike to dispense with vegetables, but the very lightest of those only should be allowed until after improvement has made some progress; we may then allow carrots, spinach, and tomatoes; lettuce and salads, and especially potato salad, should be strictly forbidden. If the patient chafes under the pro-

hibition of all kinds of preserves, he may, when convalescent, partake of stewed cranberries, strained and sweetened. Dyspeptics cannot bear raw fruit at all.

In all cases where circumstances will not permit the diet which has been described, a milk diet will be the best thing. Or when place and time are favorable, Krukenberg's direction, "When you are hungry, eat buttermilk; and when you are thirsty, drink buttermilk," should be observed. This milk, freed from the large mass of caseine, is a real panacea, and a dietary course of it is easily carried out in the country during the summer season. But caution prescribes that it should not be taken simultaneously with other food, as the rule not to drink when you eat, and not to eat when you drink, is even more imperative for dyspeptics than for persons suffering from adiposity. Patients are most difficult to manage in regard to their diet after they begin to feel better; and when, in consequence of their long fasting and their necessarily reduced condition, a strong desire for food is manifested, an adequate addition of fat of the proper consistency will greatly lessen the danger of excess, as will be mentioned hereafter.

Of the greatest importance in cases of tympanites is the local application of water, preferably the "Neptune belt," since it acts as a desiccative upon the skin. If the sensibility of the skin is impaired in a high degree, we may, instead of cold water, dip the cloth in a solution of salt. The "Neptune belt," is best applied over night, like the Priessnitz bandage, and can be followed in the morning, first by moist and afterward by dry friction.

Sitz baths of from ten to fifteen minutes' duration, twice a day, are of excellent service, in case the rectal sphincters are contracted, or hot and sensitive. Water may be used at about 50° to 55° C., and in the course of time the temperature can be further reduced, as patients get easily used to it. After a sitz bath the spasmodic contraction of the anus will rapidly cease, and the swelling of the mucous membrane subside. The piles empty themselves and shrink, flatulency disappears, eczema in this region will heal without further treatment, so will fissures, and operative treatment for spasmodic strictures becomes superfluous. There is still a prejudice against the use of sitz baths for abscesses around the anus, for the reason that tuberculous foci are often found there, with consecutive rectal fistulæ, and it has been supposed that sitz baths cause congestion of the lungs. We take no share in this view, and would merely raise the temperature in cases where the rectal walls are lax. When lukewarm full baths are not deemed necessary, cold, moist, and afterward dry frictions should take their place.

Thymol in Cholera Infantum.—Ungar uses the following with good results:

Thymol	gr. 2¼.
Spts. vini gallici	ʒvj¼.
Aquæ destill.	ʒvj½.

Of which teaspoonful doses are to be used as the physician's judgment dictates.—*Revue Générale de Clinique et de Thérapeutique*, June 30, 1887.

Does Curetting the Interior of the Uterus Destroy the Possibility of Conception?—Heinricius, of Helsingfors, Finland, reports 60 cases of fungous endometritis treated by curetting the endometrium: 25 of these cases followed parturition or abortion. Among these 25 patients 15 became pregnant after recovering from the treatment, of whom 5 were less than thirty years old, 8 less than forty, and 2 more than forty. In the 10 cases remaining there was no report from 1; 1 was a widow; 1 was thirty-nine years old, and 7 were over forty. Of the 35 cases whose endometritis was not caused by pregnancy, there was no report of 6, and 1 died; of the remaining 28 only 1 conceived after treatment. In all, of 52 patients on whom curetting was done, 16, or thirty per cent., afterward conceived. Pregnancy occurred twice in the fifth, once in the eighth, and once in the fourth week after recovery among these patients.—*Centralblatt für Gynäkologie*, July 2, 1887.

Experimental Insertion of the Ureters in the Rectum.—At the annual meeting of the Italian Surgical Society, held at Genoa in April, 1887, Professor Novaro, of Siena, read a very interesting communication on an experimental operation performed in January on a dog, for the insertion of both ureters in the rectum. The operation was successful, and the dog is now living and doing well. This operation was partially, and without good success, attempted by Gluck and Zeller, of Berlin. Bardenhauer, of Cologne, succeeded with only one of the ureters. Professor Novaro thought that in cancerous tumors of the bladder the complete extirpation of the bladder ought to be performed in two operations, reserving the explorative for the last. Scooping such a fragile organ only resulted in harm; moreover, only arrested the hemorrhage for a few days. The members applauded Professor Novaro for his successful result.—*Chicago Journal and Examiner*, May, 1887.

Birth during Maternal Syncope.—Freyer, of Berlin, in a work of medico-legal value, has made exhaustive studies of the literature of the subject, from which he draws the following conclusions:

1. The possibility of birth during maternal syncope is undoubted, and proved by many observations.

2. It is probable that this happens during concealed parturition much more frequently than under ordinary circumstances.

Phosphate of Sodium Hypodermatically in Phthisis.—Baratoux claims good results from the following:

R.—Sodii phosphat.	1 part.
Sodii sulphat.	1 part.
Aquæ destill.	15 parts.—M.

S.—Filter before using. Injections of from forty-five to ninety minims may be made once or twice weekly, in the sacro-lumbar region. These injections are followed by fever, cerebral excitation, and a feeling of fatigue for one or two days. A feeling of general improvement follows, the appetite returns, perspiration lessens, and expectoration loses its purulence. Gain in weight has been observed.—*Revue de Thérapeutique*, July 1, 1887.

The Dangers of Antifebrin and Antipyrin.—Two articles have recently appeared in the Hungarian medical journal *Gyógyászat*, in which the profession is

warned that acetanilide, or antifebrin as it is called, though it is not without value, is an uncertain, and indeed a dangerous antipyretic. DR. GÉZA DULÁCKSKA finds, after giving the drug a prolonged trial in the hospital, that small doses may bring down fever, but that in some cases even three-grain doses produce violent sweats, prostration, and hemorrhage or cyanosis. It does not appear to him to exert any favorable action on the course of the disease itself, being thus inferior to salicin, resorcin, and ichthyol. If given at all in fever, its action requires to be very carefully watched. In certain neuroses, however, Dr. Dulácksha has found it very useful, and as the doses required were smaller, he is disposed to recommend its employment in such cases, as it appears to be free from danger. In a case of severe trigeminal neuralgia, in which quinine, gelsemium, and morphia had produced but little improvement, three grains of acetanilide were given night and morning without effect; seven grains and a half were then ordered, divided into ten powders, one to be taken every two hours. This produced a great improvement, and after ten days of this treatment the cure was complete. No unpleasant effects beyond some nocturnal perspiration showed themselves. Two other cases, where severe pain was associated with meningo-myelitis and syphilitic tabes respectively, which had been treated in various ways unsuccessfully, were greatly benefited by acetanilide, no unpleasant effects being produced. DR. BIRO gave acetanilide in eighteen cases of various kinds, including typhoid, croupous pneumonia, pleurisy, polyarthritis, tuberculosis, and phthisis, in doses varying from a grain and a half to forty-five grains per diem, and was much struck with the uncertainty of its action, an effect being sometimes produced by a grain and a half, while at others ten or eleven grains had no effect at all. Most of the patients complained of chilliness, while cyanosis and irregularity of pulse occurred in several cases. In one case, where seven grains and a half had been taken, there was a severe rigor followed by cyanosis, sweating, and an irregular, thready pulse, the symptoms being so alarming that recourse was had to brandy and hypodermatic injections of ether. In another case, in which acetanilide had been given for eleven days, similar symptoms presented themselves, together with clonic spasm of the lower extremities, reminding one of the symptoms in anilin poisoning. Altogether, Dr. Biro thinks that the evil effects of acetanilide are so great that it cannot be recommended for general adoption.

Two Scandinavian physicians have recently written on the use of antipyrin, the apyretic properties of which they unreservedly admit to be the rule. Some exceptions, however, were observed. Thus DR. WETTERDAL, of Upsala, found in one case a rise of temperature during the first hour after a thirty grain dose of more than 1° F. Rigor and collapse never occurred in any of his cases. Copious sweating, however, was observed at times, over which atropine exerted no control. A rash with bluish-red spots on the face, as described by Wising, was also occasionally noticed. In some cases cinchona was advantageously combined with antipyrin. Dr. Laache, who made a special study of the action of antipyrin in phthisis, found that, though as a rule it brought down the hectic very satisfactorily, in one instance it produced, at first at least, a contrary effect, the temperature rising very markedly after a thirty grain dose. It afterward fell gradually, reaching a point decidedly below the normal. Simultaneously with the rise a rash appeared, and the patient complained of a burning sensation in the mouth and eyes and along the œsophagus. Curiously enough, the patient had previously taken antipyrin for a longer period without having experienced any unpleasant effects. The sample could not well have contained any poisonous admixture, as other patients took it with impunity.—*Lancet*, July 9, 1887.

A CONVENIENT APPLICATION FOR INSECT BITES.—BERNBECK uses the following:

Flexible collodion . . .	19 parts.
Salicylic acid	1 part.

Or,

Flexible collodion . . .	1000 parts.
Bichloride of mercury . . .	1 part.

—*Wiener Presse*, July 10, 1887.

THE PERCENTAGE OF SUCCESSFUL SECONDARY NERVE SUTURES.—MR. BOWLBY, of St. Bartholomew's Hospital, in a series of articles on injuries of nerves, reports the following results of suture in the *Lancet* of July 16, 1887:

The value of the operation of secondary suture can only be judged by a clinical study of patients, and by reference to recorded instances. Time does not permit me to describe in detail the clinical features of the various cases I have watched, or to do more than tabulate the records of other surgeons. For the present, therefore, I must ask you to accept this summary.

The following cases of secondary suture were performed in St. Bartholomew's Hospital up to December, 1885:

Median nerve: successful, 1; partially successful, 4; failure, 1—total, 6. Ulnar nerve: successful, 2; partially successful, 5; failure, 3—total, 10. Musculo-spiral nerve: successful, 1. Median and ulnar nerves: partially successful, 1. Grand total, 18—viz.: successful, 4; partially successful, 10; failures, 4.

Cases of secondary nerve suture recorded in surgical literature up to December, 1885:

Fifth cervical nerve: successful, 1. Median nerve: successful, 3; partially successful, 5; failure, 3—total, 11. Ulnar nerve: successful, 5; partially successful, 1; failure, 3—total 9. Musculo-spiral nerve: successful, 11; greatly improved, 3; failure, 2—total 16. Radial nerve: successful, 1. Median and ulnar simultaneously: successful, 1; partially successful, 2; failure, 3—total, 6. Median and radial simultaneously: partially successful, 1. Sciatic nerve: successful, 1; improved, 1; failure, 1—total, 3. Popliteal nerve: improved, 1. The above cases give a grand total of 49, of which 23 were successful, 14 partially successful, and 12 failures.

If the cases recorded by myself be added to those recorded by other authors, the totals will read thus: successful, 27; partially successful, 24; failures, 16—total, 67.

In drawing up the above summary I have been very careful not to include amongst the "successful cases" any but those in which there appeared to be either a complete or almost complete restoration of function.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE. . . . . $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

PHILADELPHIA.

SATURDAY, AUGUST 20, 1887.

THE DIAGNOSIS OF CANCER OF THE STOMACH.

THE symptoms of cancer of the stomach are often so obscure, so misleading, and sometimes so entirely latent as to baffle the most experienced diagnostician, and the same remark may apply, with lesser force, to the physical signs of the disease. The cases most easy of diagnosis are certainly those in which a well-marked tumor may be felt in the epigastrium, a tumor, however, that may be confounded with neoplasms of liver, pancreas, intestine, and lymphatic glands, with biliary calculi, and simple inflammatory thickening of the anterior wall of the stomach.

Of the latent forms of the disease, those in which neither tumor nor decided gastric disturbance is present, a diagnosis, until within a recent period, could only be made by the most careful exclusion. At present, however, thanks to the labors of several German and French observers, we are in possession of certain facts which, taken singly, are of material aid in the diagnosis of gastric cancer, and, when coexistent, are pathognomonic of that affection.

In diagnosis of cancer of the stomach the greatest significance is to be attached to the absence of free hydrochloric acid from the contents of the viscus. In testing for this acid, certain precautions, emphasized by RIEGEL, in the *Zeitsch. für klin. Medicin*, Bd. xii., are necessary. In the first place, the stomach contents should not be examined within three hours after eating. Secondly, vomited matters are not suitable for examination, because emesis generally takes place within the proscribed period, and the chemical reactions are disturbed by large quantities of bile and mucus.

The technique of this test is both mechanical and chemical. The gastric contents are first withdrawn by the stomach-pump, or siphon, and the secretions may be stimulated by the introduction of a small amount (100 cubic centimetres) of ice-water, followed in ten minutes by a smaller quantity (3 cubic centimetres) of water of a much lower temperature. The whole is withdrawn, and submitted to the following tests: First, the presence or absence of free hydrochloric acid is determined; secondly, the digestive power of the liquid is ascertained.

As tests for the hydrochloric acid, the following substances are employed: Methyl-violet, lacmus, tropæolin, congo-red, gentian-violet, etc. In all his examinations, Riegel employs several tests, and, with regard to methyl-violet, he declares that, in the examination of several thousand specimens of gastric juice, he did not encounter one that digested well and gave no reaction with this substance; and, on the other hand, the specimens that gave the reaction always digested well. This important test is thus applied: Into each of two test-tubes are poured 50 c.c. of distilled water, followed by 2 drops of a 2 per cent. solution of methyl-violet. Into one of the tubes is now added, drop by drop, the fluid obtained from the stomach; to the other is added an equal quantity of pure water. If free hydrochloric acid be present in the gastric contents, the fluid in the first tube will turn blue, while, in the latter, it will retain its violet hue. According to RENAULT (*Revue Générale de Clinique et de Thérapeutique*, 16 Juin, 1887), methyl-violet may be replaced by gentian-violet, which gives the same reaction.

While there can be no doubt that the absence of hydrochloric acid from the stomach contents is a most important point in the diagnosis of gastric cancer, the general acceptance of the fact has been retarded by the unwarranted claims that have been made regarding it. For example, Von den Velden has formulated the law: "When hydrochloric acid is absent from the liquid withdrawn from the stomach, such absence is due to a cancerous neoplasm." This statement is refuted by the observations of Riegel.

In the course of the last year Riegel studied 16 cases of cancer of the stomach, in 5 of which the diagnosis was confirmed by an autopsy. In these 5 cases he made 154 analyses of the contents of the stomach with a digestive test and quantitative estimation of the amount of acid present. In none of these numerous analyses was free hydrochloric acid found, and in no instance did the filtrate of the stomach contents possess the power of digesting albumen. In one of the cases, hydrochloric acid, in large dose, was given soon after meals, but here, also, at the time of examination, free acid could not be found, and the gastric juice was without digestive power. In this case, on the days of the administra-

tion of hydrochloric acid, the acidity of the stomach contents, at the time of examination, was less than on the other days, which paradox is explained by the fact that hydrochloric acid prevents fermentation, and, therefore, lessens the amount of organic acids, especially the lactic, on which substance largely depends the acidity of the stomach in cases of carcinoma of that organ.

In 8 of the 11 remaining cases, 120 analyses failed to find either free hydrochloric acid or digestive power. In the remaining 3, there was found, at first, a very weak hydrochloric acid reaction and feeble digestive power. They were, therefore, regarded as beginning cases of carcinoma. Later, free acid was no longer found.

From these observations Riegel concludes that, in the gastric juice of a cancerous stomach, as a rule, both free hydrochloric acid and digestive power are absent, and that, on the other hand, if, in any case, free hydrochloric acid and normal digestive power are present, carcinoma may be excluded in spite of the most decided symptoms of that disease. He denies having ever asserted that the mere absence of hydrochloric acid from the gastric juice compels the diagnosis of gastric cancer, but believes himself to be the first to have demonstrated the absence of hydrochloric acid in other affections, such as amyloid disease of the mucosa, toxic gastritis, and continued reflux of the bile.

A search for enlarged lymphatic glands should always be made in cases of suspected cancer of the stomach. Troisier, of France, has recently called attention to the diagnostic importance, in this disease, of enlargement of the supraclavicular glands, a fact previously noted by Henoch, in 1863. It is stated by Renault (*loc. cit.*), that Jaccoud always examined the glands of the inguinal region in cases of gastric cancer. Enlargement of the supraclavicular glands has also been observed in cancer of the œsophagus, of the lung, of the pleura, and even of the uterus; but in the absence of symptoms of disease of those parts, it is confirmatory of the symptoms of cancer of the stomach.

Certain hæmatological researches of Quinquaud, are of undoubted value with reference to the diagnosis of gastric carcinoma. Occupying himself particularly with the differential diagnosis between dilatation of the stomach caused by cancer, and simple dilatation, he found, in the former, a much greater diminution in the amount of hæmoglobin in the blood. In health there are to every 1000 parts (grammes) of blood 125 of hæmoglobin, capable of absorbing 240 cubic centimetres of oxygen. In simple dilatation the figures representing the amount of hæmoglobin and its power of absorbing oxygen are 80 and 174, while in dilatation caused by cancer, they do not surpass 52 and 100. With this reduction in the amount of hæmoglobin, the corpuscles are correspondingly reduced in number, and frequently assume the characters, increased size, and altered shape, of the blood of pernicious anæmia.

Excuses for failure to make a diagnosis in cases of latent gastric carcinoma are only admissible when all the means to this end have been employed with negative results.

Leaving out of view the stomach symptoms proper, which are often misleading, it is believed that a chemical and digestive test of the secretions of the organ, a proper examination of the blood, a careful search for enlarged glands and cancerous cutaneous nodules, and, finally, a quantitative estimation of the amount of urea in the urine, will furnish facts sufficient for a positive expression of opinion in every case of real or supposed gastric carcinoma.

With reference to the excretion of urea, Rommelaere, of Brussels, held the opinion that cancer was always present when the amount, for twenty-four hours, was below 150 grains; and, although it has since been shown that figures as low may be reached in other states of inanition, the fact, when existent, has a decided diagnostic value.

For an excellent collocation and digest of our present knowledge of gastric cancer, with special reference to its diagnosis, the reader may consult with advantage, the already quoted article of Renault.

SALOL.

Although the coal-tar group has, as we have often remarked before, seemed an inexhaustible storehouse of medicinal substances, we have had lately introduced into general use a substance known as the salicylate of phenol, or salol, which differs from most of the other drugs of its class in that it is composed of two derivatives of coal tar, namely, carbolic and salicylic acids. Salol was first introduced to the profession by Sahli, in Berne, in April, 1886, and has since been very generally tested at the bedside.

Perhaps the most general consideration of its virtues as yet published is that of Georgi, in the *Berliner klin. Wochenschrift*, 1887, Nos. 9, 10, and 11, who unqualifiedly recommends its use in a large number of different diseases, particularly those connected with a rheumatic taint. He also believes it to possess marked antipyretic power in all of the ordinary fevers, and declares that as an antiseptic it surpasses most of its competitors by reason of its power and lack of disagreeable odor. It would be impossible here to enumerate all the conditions in which he has found it of value, and the very multiplicity of these conditions would throw reasonable doubt over its worth, but for the fact that other observers have established some of his assertions as facts.

Perier and Patein, in the *Revue de Chirurgie*, of July 10, 1887, have recorded favorable result when using salol as a substitute for iodoform as a surgical dressing. Thus in the case of a man suffering from an extravasation of urine, with gangrene of the part, iodoform was used as a dressing for about six weeks without marked improvement, but as soon as salol was substituted healing took place rapidly. In the case of an amputated finger, healing took place by first intention when salol was used as the dressing, and these observers think it a substance of no small value.

When given internally the dose is usually from 15 to 30 grains, and Sahli has taken as much as 120 grains without producing any ill results, other than slight ringing in the ears. Georgi has also found it useful in the form of a wash for stomatitis and erysipelatous inflammations, and, altogether, the reports made upon this drug so far are so encouraging that it certainly deserves at least a fair trial by the profession in general.

CONSERVATIVE MIDWIFERY.

Sufficient time has elapsed since the introduction of antiseptics in midwifery for the extreme and its reaction to have had their place, to be succeeded by the position of the safer middle ground. Thanks to the studies of those having the principal maternities of the world in their charge, we are now able to estimate the value of different treatments of the puerperal state, and deduce rules for the individual practitioner. No matter what the prejudices of the individual may be, the study of thousands of puerperal women by competent observers must yield facts whose import is binding upon all who take the responsibility of the care of human lives.

In the *Deutsche medicinische Wochenschrift*, No. 25, Leopold, of Dresden, states the results obtained in a year's practice in the Frauenklinik, where, from May, 1886, to May, 1887, 1403 women were confined, among whom there was not a single case of septic infection contracted in the clinic. Among the last 500 confinements there was but a single case of the sequelæ of puerperal complications, and that a mild case of parametritis. The total mortality was 1.2 per cent. from all causes, and seven Cæsarean sections were among the operations performed. These results were obtained by thorough cleanliness; by the use externally of 1 : 4000 sublimate solution to disinfect the woman approaching labor. The greatest stress is laid upon the disinfection of those who examine puerperal cases. Most important is considered the thorough cleansing of the hands, nails, and forearms for five minutes with brush, soap, and warm water. Then follows cleansing in warm 1 : 3000 sublimate solution with brush and soap, and, finally, immersion for half a minute in 1 : 1000 sublimate solution. Especial stress is laid upon the soap and water cleansing. In this clinic practical instruction is given constantly. Injections and all interference with the patient are resorted to as seldom as possible.

In *Le Progrès Médicale*, No. 25, Budin reports a year's service at the Paris Charité. Among 1349 cases there was a total mortality of 1.55 per cent.; from septic infection 0.29 per cent. Corrosive sublimate, 1 to 2000, 3000, and 4000; boric and carbolic acids and iodoform are used. Students and midwives are instructed.

In the *Archiv für Gynäkologie*, Band xxx. Heft iii., Credé, of Leipzig, expresses his decided convictions in favor of non-meddlesome midwifery, and bases his belief on the critical study of 8000 puerperal women. He expresses his view that what is needed is a rule of practice under all circumstances the safest in hospitals or dwellings. He cites 2355 cases with 0.3 per cent. mortality from sepsis. He lays stress upon preventing loss of blood as far as possible; on thorough disinfection of all which has to do with the patient; and on thorough antisepsis when interference is demanded. Regarding vaginal and intrauterine douches, he remarks, "The statement made in so many case histories that the patient's condition became worse '*in spite of*' antiseptic vaginal and intrauterine injections diligently used would be more correctly rendered in many cases if the word '*because*' was substituted for 'in spite of'". He reports a septic mortality of 0.6 per cent. in the Poliklinik, where the conditions are essentially those of private practice, and he indicates this as what, in our present knowledge, in private practice might be expected. He does not consider increased body temperature and pulse-rate, without decisive symptoms, as indicating disease, and thinks the profession and laity far too readily frightened by this cause. He advises practice in *external* examination by palpation; internal examination *almost never;* restriction of manipulation of lying-in women by students. He considers it of the greatest importance to puerperal women that "Their internal organs of generation be left entirely undisturbed for the first eight or nine days after parturition (neither examined, injected, nor in any way manipulated)." In the presence of disease or injury at parturition they are not to be disturbed while the disease lasts, or while wounds and lacerations are not yet healed.

It is only ripe experience which can give an honest thinker convictions such as these. The great restriction of vaginal manipulations in midwifery is an innovation in the teaching of the present day, which encourages students to depend upon it for diagnosis. There is no question of the soundness of the views expressed by the authorities cited, and insistence upon the thorough performance of the

essentials of antisepsis and thorough knowledge of the anatomy and physiology of the parturient will banish injurious interference, and are the duty of practitioners and teachers.

THE fifty-fifth annual meeting of the British Medical Association convened at Dublin, on August 2d. A large and enthusiastic attendance is reported, and the proceedings were of unusual interest. The address in medicine, by Professor Gairdner, of Glasgow, and the address in surgery, by Professor Hamilton, of Dublin, with the historical retrospect by the President, Professor Banks, of Dublin, were especially interesting and valuable. The Association now numbers over 11,000 members, and the total circulation of its Journal exceeds 13,000; its affairs are in a condition of the highest prosperity.

REVIEWS.

A MANUAL OF TREATMENT BY MASSAGE AND METHODICAL EXERCISE. By JOSEPH SCHREIBER, M.D., Member of K. K. Gesellschaft der Aerzte of Vienna, etc. Translated, with the Author's permission, by WALTER MENDELSOHN, M.D., of New York. 8vo. pp. 285. Philadelphia: Lea Brothers & Co., 1887.

MECHANO-THERAPY, since the dawn of rational pharmacology, is a recent science; and the number of new works which have lately appeared on this subject are a measure, in part at least, of its importance and of the consideration which is bestowed upon it by the leaders of therapeutic research. The work before us is one of five which have been issued from the German medical press alone during the last five years. It is probably the most practical, and it is certainly better illustrated than any of its predecessors. Its aim is to elucidate the mechanical methods by cases which happened in the experience of the author, and to give such practical hints as will facilitate the execution of the various manipulations. After discussing the physiological effects of massage and of gymnastics, it defines the diseases to which mechano-therapy is applicable. Among the more common diseases which are amenable to its influence are sciatica, cervico-brachialgia, trigeminal neuralgia, myalgia, torticollis, sprains, chronic catarrhal gastritis, phthisis, neurasthenia, etc.; a number of which are illustrated by the citation of interesting cases.

It is to be regretted that the author does not even refer to probably the only scientific physiological work which has been done to show the effects of massage on the exhausted muscles of frogs. We allude to the interesting experiments which were performed by Zabludowski in the Berlin physiological laboratory, under the direction of Prof. Kronecker, and which were published as long ago as 1883.

With this omission, the work, so far as we can see, is one which meets every indication, and we can frankly commend it to the profession.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, held at Long Branch, N. J., July 21, 22, and 23, 1887.

Specially reported for THE MEDICAL NEWS.

(Concluded from page 194.)

FRIDAY, JULY 22D.—MORNING SESSION.

DR. ISAAC OTT read a paper on

THERMOTAXIS.

He called attention to the increase of temperature upon nerve irritation, and after the administration of atropia, and to the rise of temperature in cases of tetanus and convulsions.

DR. SPITZKA mentioned two cases of chorea, the temperature in one case rising to 104° and in the other to 107°; he could not account for the rise except by the strong muscular action exhibited. He had also seen a fatal case of chorea in which the temperature was 103°.

DR. C. L. DANA reported

A CASE OF ANENCEPHALIA ILLUSTRATING THE SENSORY TRACT.

The case was that of a male child born at full term, weighing 8 or 9 pounds; there was no deformity, except that the head was rather peculiar, being very long and narrow; the bones were freely movable, the eyes were kept closed; the child died on the second day. At the post-mortem a yellowish fluid squirted out from the brain, the first nerve was not fully developed, the arterial supply was inferior and undeveloped in some of its branches, the pons Varolii was small, as was also the spinal cord.

DR. GEORGE W. JACOBY, of New York, presented a paper on

THE TREATMENT OF NEURALGIAS BY MEANS OF INTENSE COLD.

He said that our methods of applying cold therapeutically have been revolutionized by the introduction into use of chloride of methyl. Since Debove first recommended this agent in 1884, he had given considerable attention to the therapeutic action of the various refrigerants, and had come to the conclusion that we possess only two which can be easily and practically utilized—the chloride of methyl and fluid carbonic acid. By chloride of methyl he has treated five cases of trigeminal neuralgia; three of from one to five weeks standing, one of six months, and one of twenty-seven years duration. In all the pain was entirely relieved after the first application. In two of the recent cases the pain returned; a second application was made and a cure resulted. In one of the other cases the pain was so much ameliorated after four applications that the patient discontinued treatment, although not entirely well, but in the fifth case he was able only to obtain relief from pain, and, although six applications were made there was no sign of permanent improvement. His conclusion is that we have in the chloride of methyl a reliable analgesic, which does not affect the general condition of the patient, and that it is invaluable in the

treatment of neuralgias for the immediate relief of severe pain.

He has used the carbonic acid in ten cases of sciatica, and he finds that it is a good substitute for the chloride of methyl so far as relieving the pain is concerned, but that its curative effect is not so great.

Dr. Charles K. Mills presented

NOTES OF SOME CASES OF MULTIPLE NEURITIS (OR MYELITIS) OF SYPHILITIC ORIGIN, WITH REMARKS ON THE DIFFICULTIES OF DIAGNOSTICATING MULTIPLE NEURITIS FROM SOME FORMS OF MYELITIS.

During the ten years he had been Neurologist to the Philadelphia Hospital, the attention of Dr. Mills had been frequently directed to a certain class of paralytic cases, in which a clear history of either syphilis or of chronic alcoholism, or of both, had always been present. Syphilis and alcoholism were so frequently factors in the production of the organic nervous affections observed at the Philadelphia Hospital, and they were so often conjoined in the history of the same case, that it was sometimes difficult to separate such cases into two subdivisions, one of which represented a type clearly syphilitic, and the other one clearly alcoholic. Sometimes, however, he had been able to do this. He had for presentation the notes of three cases in which the past history of the patient, or the results of treatment, or both, indicated a syphilitic origin of the disease. With reference to alcohol, he said that the cases of the same class clearly due to alcohol alone, presented almost identically the same clinical features as those shown by the purely syphilitic cases. Purely alcoholic cases did not, however, so well respond to specific treatment, and sometimes would not respond at all to such treatment. During the last ten years he had seen at least a dozen cases similar to those to be detailed, cases, the majority of which recovered under specific treatment, with the help of massage, electricity, tonics, and time.

Many interesting questions might be suggested by a study of cases such as these. He had, for instance, often been at a loss, from any known rules of diagnosis, to differentiate clearly their local pathology. They presented such phenomena clinically, that, he had no doubt, in an era of "multiple neuritis" they would be classed as examples of that affection, although almost all, if not all, the symptoms could be easily traced to a spinal lesion. These cases, among others, had led him to a conclusion which he regarded as philosophical, and which he believed was borne out by the facts, namely, that in practice we had frequently not multiple neuritis alone, and not myelitis alone, but a concurrence of these inflammatory conditions in the same case. At a meeting of the Philadelphia Neurological Society, held November 22, 1886, he had presented some remarks on this concurrence, and also upon the concurrence of encephalitis with neuritis or myelitis, coming among other conclusions to the following: We may have—1. Cases of multiple neuritis, pure and simple, but such cases are rare. 2. Cases in which the multiple neuritis is associated with myelitis.

Dr. Mills related the histories of three cases, and then said he desired to elicit a discussion on the differential diagnosis of multiple neuritis from some forms of myelitis, and especially diffuse myelitis and poliomyelitis. The differential features given by Chapin, Starr, and others, he regarded as insufficient. Some of them were misleading. Common both to multiple neuritis and myelitis of the forms indicated were atrophic paralysis, lost knee-jerk, and degeneration reactions, according to the best observers. Pain and tenderness, severe in character, distinctly localized to nerve-trunks and muscles, and the absence of symptoms of paresis or spasm in the bladder and bowels seemed to be the most definite marks of multiple neuritis, but could even these be regarded as positive, or, at least, absolute? It was certainly fallacious to decide in favor of neuritis because of gradual onset, because the cases got well, because the paralysis was progressive and ascending, or because of the presence of numerous and persistent sensory manifestations.

When the nerves and central organs were both involved it was difficult to say which was first involved; there are some forms of these diseases which are painless and others where the pain is great. He considered there were cases where it was impossible to discover whether the disease were central or peripheral.

Dr. Edes said that he reported a case some years ago in which he found symmetrical lesions in the cord; there was the usual amount of asthenia with rapidly advancing paralysis and atrophy below the knees and elbows; the case resulted fatally. He thought Dr. Mills was right, and that these two things may coexist, but whether the degeneration of the cord was owing to neuritis he would not be certain. He thought the tendency was to call these cases neuritis.

Dr. Putnam remarked as to the connection of neuritis and disease of the anterior columns of the spinal cord, the pain felt in poliomyelitis is really of neuritic origin; he made a post-mortem in a case in which the pain was intense with the paralysis at the onset of the disease, although the nerves were not examined he could conceive that there was no doubt that they were affected; the spinal cord was affected throughout the columns, but confined to the gray matter. He had seen cases of pain with a loss of sensibility where the cord appeared to be healthy, but where the brain had spots of softening, and the arteries were greatly thickened in the central nervous system. As Dr. Mills had suggested, the different types differ so strongly that we have to conclude we are dealing with a symptom of disease, and that the spinal cord and peripheral portion are related in some way.

Dr. Lloyd suggested the use of electricity as a means of diagnosis in these cases.

Dr. Starr did not think this means could be depended upon, as the intensity of the disease was so varied. He thought a great many cases of poliomyelitis begin without any sensory symptoms at all, and where they do occur at the beginning, the question comes in as to whether it is not neuritis. He did not remember seeing any cases in which the cord was affected equally on both sides, one arm would be affected more than the other and so it would be with the legs. In multiple neuritis both sides were affected similarly; as a rule, cases that he had seen during the past year followed out that idea. He considered it a mistake to call all cases that recover neuritis; neuritis is not always favorable in its course, but it is more favorable than the other; there is a form of subacute poliomyelitis which may correspond with neuritis, pain and tenderness being points of great value in diagnosis.

DR. DANA considered alcoholic paralysis to be multiple neuritis; in these cases he had found the greatest variety of symptoms; in those cases of alcoholic neuritis we find neuritis alone, and in myelitis, myelitis alone, but cases have been reported where they have been combined.

DR. MILLS by no means asserted the constant coexistence of the two diseases, but his desire was for the Association to discuss the different diagnostic points; he did not think electricity, as suggested by Dr. Lloyd, would be of great value; he felt convinced that poliomyelitis began with sensory symptoms at times but that the cord in these cases was attacked by a more general inflammation which limited itself in time to the horns.

DR. E. D. FISHER, of New York, reported

A CASE OF BULBAR PARALYSIS

in a young married woman who had been under his care for a year and a half. The expression of the face then was characteristic of the disease, the lower lip hanging down and saliva flowing from the corners of the mouth; the tongue was small and atrophied and she could swallow with difficulty; examination of the larynx was almost an impossibility; reflexes were normal, the disease being confined to the hypoglossal and lower portion of the facial nerve; speech at length became utterly impossible. The mind was not affected, but the patient was very excitable and emotional. Emaciation then commenced; deglutition being extremely difficult, her food was confined to fluids. At night severe attacks of dyspnœa appeared, the patient being unable to cough. At the autopsy the floor of the fourth ventricle, the region over the hypoglossal nerve, was small and pale, the specimen after hardening showing an almost entire disappearance of the cells; the facial nerve was not involved in a marked degree.

He thought the disease was probably induced by a defective blood supply in its early stages, and increased supply of blood to the parts later, but of a non-inflammatory nature, its purely local character being due to the arterial distribution of the parts.

The Association then approved of the scheme for the

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS,

and Dr. Landon Carter Gray was appointed its representative in the Executive Committee of the Congress, and Dr. Charles K. Mills alternate.

The following were then elected

OFFICERS FOR THE ENSUING YEAR,

President.—Dr. James J. Putnam, of Boston.

Vice-Presidents.—Drs. Wharton Sinkler, of Philadelphia, and B. Sachs, of New York.

Secretary and Treasurer.—Dr. Graeme M. Hammond, of New York.

Councillors.—Drs. George W. Jacoby, of New York, and Robert T. Edes, of Washington.

The Association then adjourned.

CORRESPONDENCE.

LETTER FROM LEIPZIG.

Sänger's Performance of Laparotomy—Lacerated Cervix in Germany.

Although the months of July and August are held as holidays in Germany in many departments of the universities, there is yet much to be seen in the line of surgery, and while the auditoriums are not so crowded with students, the professors still continue to operate, and, with the exception of a short holiday, which is very apt to fall in August, they devote much time and courteous attention to their visitors, especially if they are specialists seeking information. Within an hour after my arrival at Leipzig I was fortunate enough to see Dr. Sänger perform two laparotomies, one for tumor of the gall-bladder, and the other for cystic tumors of the broad ligament and ovaries.

The *technique* was perfectly aseptic, and conducted in a manner with which we are all now familiar, insuring the regular and perfect recovery which usually follows.

The gall-bladder had formed a large retention cyst, the stoppage being due to an unknown cause. This cyst was first stitched carefully to a short vertical incision at the outer margin of the right rectus by the navel, and was next, after the formation of close adhesions shutting off the remainder of the peritoneum, which occurred in six days, opened by Paquelin's cautery.

One of the cystic tumors was parovarian, the size of a small cocoanut, and the other a small dermoid cyst of the left ovary. The incision was made long enough to slip the larger cyst out intact; the pedicle was tied by transfixion, and again a separate ligature was thrown around the whole stump. Both stumps were treated in this way, and the cut surfaces carefully burned with Paquelin's cautery. This last procedure is followed as an antiseptic measure and one greatly limiting the amount of exudation.

I was particularly interested in the method of tying, as it is exactly that which my own experience has taught me to adopt. The dangers of immediate hemorrhage in a tie which pulls up the broad ligament in the shape of a cone are greater than is generally believed to be the case, and a transfixed tie seems peculiarly liable to inversion. This may result more from a tendency to cut the stump cup-shaped rather than from any mechanical difficulty. I am, however, sure that the two ties combined afford the utmost possible safety in the case of a broad pedicle tending to roll out.

The tie used by Prof. Gaillard Thomas is employed in Germany also, and though in some respects similar, is practically different, the method here used possessing a distinct advantage in that the last tie is accurately applied in exactly the most convenient place for the thread to hold securely, and is conveniently added just before dropping the pedicle.

Our workers at home will be both surprised and pleased to hear that "laceration of the cervix uteri" has at last found here an advocate in Dr. Sänger, who fully understands the subject in all its bearings. Although this is one of the minor operations in gynecology, and one indeed which at home has been much injured by the *furor operativus*, one first realizes in coming abroad what a world of good the operation is capable of doing, and what a vast field is open for it in Germany, England, France, and Italy. While last year I was shown well-marked lacerations with extensive eversion of the cervical mucous membrane labelled "erosion," I now see cases which have been very neatly operated upon and *cured*, and I see still others in process of preparation for operation, and hear remarks upon the *rarity* of real erosion.

The same misunderstanding is general in Great Britain, and was especially apparent at the meeting of the Gynecological Section of the British Medical Association, at Brighton, in 1886.

Nothing better defines the great difference between the practice of forty years ago and to-day in America, and the great steps we have taken in the advance in practical surgery, than this very subject of lacerated cervix. Twenty years ago, the "erosion" which was so universally found and so invariably accompanied by other signs of disease, was treated directly by cauterizing and destructive agents of various sorts; and one saw in consequence (in fact, sees yet) the well-known small, hard, gristly cervices, in which the canal could scarcely be found, or even penetrated by a bristle. Yet it is a tribute due to our predecessors to acknowledge that, on the basis of a false pathology, they still often attained by their practical genius excellent results. By the nitrate of silver method, especially, the great, spongy, infiltrated lips were thus destroyed and shrunken, and the patient often relieved. Now the tedious, uncertain, and, in case of consecutive pregnancy, even very dangerous, method has been, in America, replaced by the rational preparatory treatment and the rational operation—thanks to Dr. Emmet; and the stimulus this one simple procedure has given to the present careful investigation and rational treatment of all other gynecological subjects, cannot be overestimated.

In Germany the matter has, however, taken another and truly a very remarkable form. In the first place, the relation between epithelial proliferation and cancer everyone knows, and the tendency of epithelium to grow in places where it is not normally found, or to invade tissues more deeply than normally, is naturally to be dreaded. In the second place, on the "erosion" (lacerated cervix) we find glandular epithelium, which belongs *inside* the cervix, extending *far outside* toward the vaginal wall (in consequence of eversion). Couple these two facts with a third, the frequency of cancer of the cervix, and we have in this apparently misplaced epithelium the simplest and most reasonable explanation possible of the origin of the *epithelioma cervicis*. Here, again, we must pay a tribute to the practical genius of our coworkers, relative to their treatment of the difficulty, holding, as they do, such etiological views. The operation prescribed for such an "erosion," which "may be now just passing into cancer," is *amputation*, and that is the reason why we see so many amputations of lacerated cervices in Germany. But this *amputation* is usually only one *in name*, being in reality a skilful *resection* of the diseased mucosa, such as we might ourselves occasionally practise, where the mucous membrane is infiltrated and diseased beyond hope of rejuvenation. The cervix is, by this procedure, somewhat shortened, but never cleaned off to the extent I have seen in amputations by the wire cautery.

A few students are in Leipzig attending the summer course in the Entbindungs Anstalt, under Prof. Zweifel, with the valuable assistance of Dr. Döderlein; others are availing themselves of the opportunities afforded in the Poliklinik, under Dr. Sänger, where a rich material and the wonderfully clear teaching of one of the best gynecologists in the world give all an inquisitive mind could ask.

HOWARD A. KELLY.

Leipzig, July 19, 1887.

IPECACUANHA IN LABOR.

To the Editor of THE MEDICAL NEWS,

SIR: Under this title an editorial in THE NEWS of July 23d, contains the following: "Carregei, in the *Revue Medico-Chirurgicale des Maladies des Femmes* of May 25th, states that from the remarkable influence ipecacuanha has over uterine hæmorrhage he has been led to employ it as an oxytoxic." And it is there remarked that the practice is by no means new, though the quantity of the medicine is much less (a grain and a half to three grains) than that heretofore employed; and reference is made to the use of the nauseating influence of ipecac in a rigid os thirty years or more ago, with the comment that it will be a great gain if so simple a remedy in such a dose will shorten the time and diminish the intensity of the suffering.

This is a curious illustration of a certain periodicity that sometimes involves and reiterates medical knowledge, and especially of the failure of a prophet to receive honor in his own country.

In the *New York Medical Journal* for November, 1878, Dr. John H. Carriger, of Knoxville, Tenn., published an interesting article, illustrated by cases, on "The Use of Ipecacuanha in Labor," where he reached the conclusion that it is "a potent and reliable uterine motor stimulant," and that its influence over uterine hemorrhage is not, as sometimes taught, "due to sedation upon the heart and arteries, . . but to its power of coördinating uterine action and stimulating tonic contraction." He believes that it exercises "coördinating influence over that condition of the uterus in which we have irregular uterine action," and further that under its use there is "a general contractility of the non-striated tissues, [and] a contraction of the capillaries as well as of the uterine tissues." He gave in labor cases two grains every thirty minutes, and had followed that practice since 1851.

This paper does not appear to have attracted much attention in this country, but in the *Virginia Medical Monthly* for February, 1880, there appeared as an original translation this extract from the *Revue des Sciences Médicales* (number and page not given): "Dr. Carriger employs ipecac for its speedy action in hemorrhage during and after parturition. He says it is a powerful drug in stimulating a weak labor and in relaxing rigidity. It also hastens labor by increasing the pains. A long labor has been speedily terminated by giving from 10 to 20 centigrammes (15 to 30 grains) of powdered ipecac." Here there is an evident error in misplacing the decimal point and then translating from that—the true dose being 1.5 to 3 grains.

I have the impression that I have seen in another American journal, a translated extract on this subject from the French of "M. Carriger," but the reference is mislaid.

In the *New York Medical Record* for June, 1882, Dr. L. F. Pitkin writes that having had his attention drawn about two years before by "an article written by a Southern physician," he has used ipecac "in several cases where the pains were irregular and the os rigid and undilatable, and always with benefit." He thinks it has a specific effect on the rigid os uteri, softening and relaxing its fibres as well as having a coördinating influence on the irregularly contracting uterine muscles,

causing them to act in harmony." He reports the details of one case where he used five grain doses with success.

An examination of the original in the *Revue Medico-Chirurgicale* makes it evident that Drs. Carregel and Carriger are identical and that the French journal is still using the material of the Knoxville physician. It would be interesting, if practicable, to follow the course of the quotation to and fro, but it would certainly be all traced in the end to the single authority.

My own interest in this matter lies in the fact that in 1876 I published my belief that ipecac is essentially a stimulant to the organic nerves and that its emetic qualities are incidental—an opinion which Dr. Carriger appears to have reached independently. In a very limited obstetric practice I have since followed his advice and always with satisfactory results.

Renewed attention is now invited to this use of two-grain doses every twenty or thirty minutes when the os is rigid and the pains irregular and ineffective. Under the circumstances it will almost certainly be found a trustworthy uterine stimulant, and by a wider experience the exact therapeutic value of the drug may be established. Respectfully,

Alfred A. Woodhull,
Fort Leavenworth, Kan., Surgeon, U. S. Army.
August 6, 1877.

NEWS ITEMS.

Rags and Infectious Diseases.—From the report on the "Transmission of Infectious Diseases Through the Medium of Rags," by Dr. C. F. Withington, incorporated in the Eighteenth Annual Report of the State Board of Health of Massachusetts, we take the following conclusions:

1. Smallpox has been transmitted through the medium of rags in a certain number of cases, small in proportion to the whole number of persons who handle rags, but absolutely numerous enough to show that unvaccinated workers in rags are exposed to an actual, if not imminent, danger of infection from this source.

2. The source of this infection is more frequently domestic than foreign rags, though the disease has been caused by the latter. This possibility of infection through imported rags accords with what is known of the tenacity of life of the variolous poison.

3. Among the rarer means whereby cholera is transmitted, are textile fabrics infected with choleraic discharges. There is evidence that clothing from cholera patients, and possibly clothing merely packed in an infected locality, has, when transported to a distance and there unpacked, caused the disease in those who have handled it, thus starting a fresh cholera focus. A proper distinction exists between clothing, on the one hand, recently removed from the body and again not long after to be put on to the body; and rags, on the other hand, which, if transported to this country, are certain to have undergone a carefully discriminative sorting and drying, and to have spent a considerable time in warehouse and on shipboard.

4. The statement that cholera has been transmitted by paper rags, rests upon a solitary case, of which the details are not complete, and on the reliability of which some of the highest authorities on cholera have cast doubt. If the case be accepted, it is one of infection by *domestic* rags, carried only fifty miles from their place of collection.

5. An epidemic affection known as "rag-sorters' disease," appears to have broken out on three or four occasions in European paper mills. It was probably, though not certainly, the disease called anthrax.

6. Authenticated instances are not to be found in which the other infectious diseases—typhus and typhoid fevers, scarlet fever, measles, and diphtheria—have been transmitted through rags; though it is to be said that such evidence, supposing the fact to exist, would be very difficult to get. Neither do the mortality tables, as shown by registration reports, show a preponderance of deaths from these diseases in the paper-making towns.

7. There is no evidence to show that rag-sorters as a class are, except for occasional cases of smallpox and a certain amount of pulmonary irritation from the dust of improperly ventilated rooms, less healthy than other persons engaged in indoor manual occupations.

8. Despite the fact that cholera is not known to have ever been conveyed to this or any other country in foreign baled rags, it is a reasonable precaution to prohibit the landing in any United States port of rags gathered in epidemically infected localities, in view of the possibility that among such rags there may have been thrown articles of infected clothing which have not been sufficiently dried and aired, or have not occupied enough time in their transportation to be devoid of danger. Such prohibitions should be limited to the time and place of epidemic infection; but all necessary precautions should be taken to make sure that rags shipped from a healthy port were not gathered or baled in an infected place.

9. As the only safeguard against the occurrence of smallpox among operatives, paper-mill owners, whether "incorporated companies" or not, should make evidence of successful vaccination an absolute prerequisite to the employment of any person in the mill, and a revaccination at regular intervals (not merely on the occurrence of an epidemic in the neighborhood) a condition of being retained in their employ.

10. As the contagion of smallpox, phthisis, and perhaps other diseases, is capable of being inspired when the particles carrying it are suspended in the air in the form of dust, and as dust, even when it carries no contagion, is irritating to the respiratory passages, every mill should have, in connection with each table in the rag room and in the dusting room, a ventilating system, preferably consisting of flues connected with an exhaust fan, so that the dust, as fast as it is disengaged, may be withdrawn from the air. The success which attends the working of such an apparatus in some mills where it is in use, is a sufficient warrant for its general introduction.

11. A law similar to that of Great Britain, imposing a penalty on the selling or giving away of infected rags from persons sick with any dangerous disease, seems desirable. Public institutions and private householders should be obliged (and not as at present, simply advised) to insure the disinfection of the more valuable articles, and the destruction by fire of all rags that have been thus exposed.

12. As domestic rags comprise more than half those used, and represent a still larger proportion of the infection likely to be carried, it follows that they should par-

ticipate in whatever disinfection is thought necessary. This fact points to the paper mill as the proper place for making such disinfection. The sulphur process would, doubtless, afford the least embarrassment to the manufacturer; the bales being opened in a tightly closed room, the rags being spread on racks, and sulphur burned in the proportion of two pounds to each one thousand cubic feet of space. The introduction of steam under pressure, the rags being similarly disposed, would be the most effective disinfection possible, but would dampen the rags to their injury, unless the moisture were dried out at once with a current of hot air.

Hospitals for Contagious Diseases.—We have several times had occasion to call attention to the importance of providing special hospitals for the treatment of those forms of contagious disease in which isolation and disinfection are of special importance. The Municipal Council of Paris has been leisurely investigating this subject for the last three years through a committee, in behalf of which Dr. Chantemps has recently presented a report which is of interest in this connection.

It is certainly time that Paris should take some steps to diminish the proportion of contagious disease which seems of late years to have been increasing within her boundaries. The only special accommodation for such diseases which she now has consists of two barracks for smallpox, one connected with the hospital St. Antoine, and containing seventy-two beds, the other at the hospital St. Louis, containing sixty-four beds.

Nor can the methods actually in use in Paris for dealing with contagious disease be considered as at all satisfactory.

Theoretically, there is a very good set of rules and regulations for such cases, but practically they are not carried out. For example, the total amount expended during 1885 for the disinfection of infected localities was $163. Disinfectants are stored at the police stations and in the municipal laboratory, but they are not used.

Dr. Chantemps proposes that two special smallpox hospitals shall be constructed, one for the northern and the other for the southern portions of the city, the two to contain 300 beds. It is also advised that two special wards for diphtheria cases be arranged in the two chief hospitals for children, at which also separate pavilions for scarlet fever and measles should be provided. Two stations for ambulances to convey contagious cases to hospitals are to be provided, each to have six separate compartments, in each of which two ambulances are to be kept. The vehicles in each division are used for cases of one disease only, the diseases thus provided for being smallpox, measles, scarlet fever, diphtheria, whooping-cough, and miscellaneous skin affections. There are also to be provided two disinfecting stations, with the usual apparatus for the use of superheated steam, etc. It will be seen that what is recommended is really needed for such a city as Paris, but it is doubtful whether anything will really be done until the stimulus of an epidemic compels attention to the matter.

While most of our large cities are better provided with means for circumscribing and destroying infection than Paris is, and make more use of them, it is, nevertheless, true that the majority of our cities of from ten to forty or fifty thousand inhabitants have no sufficient hospital accommodation, means of transportation, or disinfecting apparatus for dealing with contagious disease, and that until they are provided with these the efforts of health officials to control the spread of such disease must be of comparatively little use.—*Sanitary Engineer*, July 16, 1887.

Pasteur's Remarks upon His Recent Election.—On the occasion of his practically unanimous election to the Permanent Secretaryship of the Academy of Sciences, Pasteur said that he wished "to devote what remains to him of existence to two purposes: one, to institute researches and to train students full of promise in a manner worthy of French science; the other, to follow attentively the work which the Academy institutes and encourages."

The Decomposition of Wood Dependent upon Living Organisms.—*A propos* to our knowledge of decomposition in animal tissues as caused by living organisms is the following, from the *Sanitary Engineer* of June 11, 1887:

Prof. A. H. Church, in a recent lecture on "Wood, Its Chemistry, Its Decay, and Its Preservation," thus alludes to the use of paraffine as a preservative of wood: "It is now believed that wood does not decay simply by the action of moisture and air, unless the germs of living beings are also present, and that is the reason why the three classes of materials which prevent decay have been found to be effective. Some of these agents altogether exclude air and water, and are termed hydrofuge substances. A coating of excessively hard paraffine, melting at a temperature of 150° Fah., excludes all the germs of those minute organisms, and prevents decay. Paraffine is absolutely indestructible, and is unaffected by alterations of temperature or exposure, consequently it offers one of the best materials for the treatment of wood in cabinet or joinery work; and although it slightly increases inflammability of the material for floors and parquetry, nothing is better than paraffine." He then mentioned substances which prevent the decay of timber which he termed of the poisonous class. "Air and moisture may be permitted to penetrate the wood, but by putting minute quantities of chloride of mercury, carbolic acid, acridine, cryptidine, or naphthaline into it, the timber will show no alteration, except that the coloring matter is changed, until the preservative substance has escaped. Then there are substances which are non-poisonous, and not hydrofuges, but which yet prevent decay and paralyze the organisms. A small quantity of the vapor of chloroform, and many other substances, are, without being actually poisonous, able for a time to prevent the decay of wood. On all grounds, therefore, the conclusion was reached that timber decays on account of the presence of living organisms, and not by direct chemical action."

Photography by Vital Phosphorescence.—Dr. John Vansant, in the *St. Louis Photographer* for July, 1887, calls attention to the curious fact that the kind of light given out by certain *animal organs*, and which evidently in its causation has some close relationship to the nervous system and vitality of the animal, and can bring about incipient decomposition in a haloid salt of silver. Moreover, it can do this through a sheet of glass of the usual thickness used for photographic nega-

tives, and, consequently, there is a possibility of producing by such light photographic positive prints.

The following experiment, copied from his notes, proves this: June 8, 1887. Just after dark, I took about a dozen fireflies (*Lampyris corusca*), which had been captured a few minutes before on the lawn, and inclosed them in a wide-mouthed vial of some three ounces capacity, having a piece of fine white bobinet (such as is used for ladies' veils) stretched over its mouth in place of a stopper. Inclosed thus, they would frequently emit the momentary flashes of greenish-tinted yellow light for which they are remarkable, though usually only one insect at the same time would flash. Every few seconds one or another would emit its light for a period which I estimated to average in each case about one-half of a second, and the frequency of the emissions could be increased by gently shaking the vial. When not flashing, the under surface of the three posterior segments of the firefly's abdomen, from which the light came, was scarcely at all luminous, but was simply of a bright yellow color. The flashing was plainly under the control of the insect, like its muscular movements. These fireflies are rather less than three-quarters of an inch long, and the segments which become luminous have, altogether, an area of only about one-eighth of an inch square. This flash is, however, quite bright, so much so that fine print can be easily seen when held close to it.

Repairing to my dark closet with the vial of fireflies, I placed it to one side, under cover, whilst I arranged and clamped a very sensitive gelatino-bromide of silver dry plate beneath an ordinary negative picture of a landscape on glass, as for contact printing.

The vial of insects was then inverted over the back of the negative, so that only the fine meshes of the bobinet and the glass of the negative with its gelatine film intervened between the firefly's light and the sensitive bromide plate. I counted the flashes, occasionally shaking the vial and sliding it over the negative, till fifty flashes had occurred.

The vial was then removed, the sensitive plate separated from the negative, and an attempt made to develop the latent image, if any existed. Alkaline solution of pyrogallol was used, and in a few minutes I had the pleasure of seeing a well-marked positive image of the negative picture appear, the plate being somewhat yellow stained, as if from too long an exposure. This was fixed in the usual way with sod. hypo sulph., and is now in my possession—probably the first picture ever *produced by the light emitted from a living animal organism.*

THE PROLONGATION OF HUMAN LIFE.—The last report of the Registrar-General in England furnishes fresh evidence of the steady progress which is making in the prolongation of human life, especially through the influence of the sanitary measures adopted during the last thirty years. The death-rate for 1886 was 19.3 per thousand of the population, which was lower than that recorded in any previous year since the registration system was started in 1837, with the two exceptions of 19 in 1885 and 18.9 in 1881. The mean annual death-rate for the six years since 1880 did not exceed 19.3, which was 2.1 below the mean rate between 1840 and 1880. This means that 339,000 persons in England and Wales were alive at the end of those six years who would have been dead if the rate of mortality which prevailed between 1870 and 1880 had been maintained. The reduction is largely accounted for by the falling off in the deaths from the principal zymotic or "filth diseases," which have sunk from an annual rate of 4.15 per thousand, between 1860 and 1870, to 3.40, between 1870 and 1880, and only 2.43 since 1880. The proportion of infant mortality has also been perceptibly diminished, falling from an average of 149 per thousand births, during the ten years preceding 1880, to 141 in the six years since then. The birth-rate itself last year was only 32.4, which is lower than in any year since 1848, and the natural increase of population by the excess of births over deaths accordingly shows a decline from 375,922, in 1884, and 371,520, in 1885, to 366,138 in 1886.—*New York Evening Post.*

NOTES AND QUERIES.

IS ANTIPYRIN A PROPRIETARY MEDICINE?

To the Editor of THE MEDICAL NEWS,

SIR: Please inform me, through the columns of THE NEWS, if antipyrin is a proprietary medicine or not? Also, if an ultimate analysis has been published, and, if so, what is its chemical formula? SUBSCRIBER.

BARRYVILLE, N. Y., August 12, 1887.

[The preparation and chemical composition of antipyrin are secrets, and it is manufactured under a patent.—ED.]

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM AUGUST 9 TO AUGUST 15, 1887.

MCKEE, J. C., *Major and Surgeon.*—Ordered for duty at Watertown Arsenal, Massachusetts.—*S. O. 181, A. G. O.*, August 6, 1887.

BROWN, H. E., *Major and Surgeon.*—Sick leave extended to August 6, 1887, on account of sickness.—*S. O. 184, A. G. O.*, August 10, 1887.

CLEARY, P. J. A., *Major and Surgeon.*—Ordered to Fort McDowell, Arizona Territory, instead of Fort Assiniboine, Montana Territory.—*S. O. 180, A. G. O.*, August 5, 1887.

MERRILL, J. C., *Captain and Assistant Surgeon.*—Ordered from Fort Klamath, Oregon, to Watervliet Arsenal, New York.—*S. O. 181, A. G. O.*, August 6, 1887.

WILSON, GEORGE E., *Captain and Assistant Surgeon.*—Granted leave of absence for fifteen days.—*S. O. 78, Department of Dakota*, August 8, 1887.

SUTER, WILLIAM N., *First Lieutenant and Assistant Surgeon.*—Ordered to return to Washington Barracks, District of Columbia, on the breaking up of the camp at Creedmoor, New York.—*S. O. 100, Division of the Atlantic*, August 10, 1887.

ANDERSON, C. L. G., *First Lieutenant and Assistant Surgeon.*—Station, Whipple Barracks, Arizona Territory) Ordered to Fort McDowell, Arizona Territory.—*S. O. 81, Department of Arizona*, August 3, 1887.

HOPKINS, WILLIAM E., *First Lieutenant and Assistant Surgeon.*—Ordered from Angel Island, California, to Fort Mason, California.—*S. O. 184, A. G. O.*, August 10, 1887.

MACAULEY, C. N. B., *First Lieutenant and Assistant Surgeon.*—Promoted to be Assistant Surgeon, with the rank of Captain, by operation of law, August 10 1887.

FLETCHER, J. E., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Monroe, Virginia, to Fort Wood, New York Harbor, N. Y.—*S. O. 180, A. G. O.*, August 5, 1887.

DICKSON, JOHN M., *Captain and Assistant Surgeon.*—Died, August 8, 1887 (station, Fort Mason, California).

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

TWO GENERATIONS OF HEREDITARY OR CONGENITAL ATAXIA: A CLINICAL CONTRIBUTION.

BY WM. M. MASTIN, M.D.,
OF MOBILE, ALABAMA.
FELLOW OF THE AMERICAN SURGICAL ASSOCIATION, ETC.

TYPICAL examples of hereditary or congenital ataxia, also designated as Friedreich's disease, are to be regarded of rare, or at least, not very frequent occurrence in the clinical records of general ataxic disorders. For, with the exception of certain well-known instances, the greater number of such recorded cases, although doubtless rightly classed among this variety of motor spinal affections, are, in many instances, lacking in some important or essential characteristic,—most frequently the distinctive feature of a clear hereditary or congenital history, and consequently fail to group together that full complexus of symptoms claimed to be representative of a separate form. Therefore, cases possessing these requisite qualities cannot be otherwise than of decided professional interest, and my purpose in this paper is simply to narrate the history of a family, embracing several cases, and extending through two generations, recently coming under observation, which seem to furnish all the necessary symptoms illustrative of this type of ataxia.

The facts and data relative to the history of the *older* generation were obtained from the brother-in-law (being also the father and uncle of the cases now living), an intelligent gentleman, whose statement throughout was clear and explicit. For the opportunity of making a careful and thorough personal examination of the cases constituting the *present* generation, together with the necessary information concerning their previous history, I am indebted to the late Dr. Joseph H. Hamilton of this city, under whose constant professional care they have been from birth, and who was able, therefore, to detail every phase in the progress of the disease from its incipiency to the present time.

Under these circumstances, I offer the following histories as constituting a complete chain of valuable and unbroken facts.

Going back three generations I learn that the grandparents of the present (third) generation were blood relatives, being first cousins. They were of French descent, were born in New Orleans, where they resided until early adult life, and then after marriage moved to Mobile. Both were vigorous and healthy people, without nervous troubles or any known hereditary tendencies, and d ed from ordinary causes at somewhat advanced ages.

FIRST GENERATION.—The result of this union was two sons and five daughters. The latter were all comparatively healthy, well-formed and well-grown, and active physically and mentally. With the two sons, however, the nervous affection first showed itself, although the manifestation of identical phenomena in these two members of the same family of children, together with its transmission through two others (sisters), as shown further on, indicates conclusively a marked and distinct hereditary influence.

CASE I.—Patrick, the eldest son, was the second child, and was born at term. He was a brunette in complexion, and up to the age of fifteen years was a vigorous, robust, healthy, and active boy. At this age, however, certain nervous symptoms began to be observed, which, at first, were characterized by an awkwardness and unsteadiness in using his legs and feet whilst walking, a shuffling and tottering gait, dragging his feet, and not lifting the toes clear of the ground, and consequently frequently stumbling and falling. Standing erect also became difficult. He complained of weakness of the entire limbs, especially the knees, and difficulty in rising from the sitting or recumbent postures. A "dropping down" of the feet when the leg was crossed, was a very noticeable feature. These symptoms progressed steadily and uninterruptedly from bad to worse, until finally the upper limbs were invaded, and after only a few years he became completely ataxic. There seems to have been no pain, or other sensory disturbance; vision and hearing were apparently normal; mental condition slightly, but not decidedly dulled, but his speech was slow, and he possessed an ungovernable temper. Notwithstanding medical attention, the disease marched steadily on, ending in a state of absolute helplessness, and he died from a general wearing out, as it were, at the age of thirty years.

CASE II.—The other son, Dominick, was the third child, and next to his brother Patrick. He was of a decided brunette type, and as a little boy, enjoyed excellent health, being about as active as children of his age. The origin, symptoms, and course of the malady with him were almost the exact counterpart of those exhibited in his brother's case. It began to be noticed at a somewhat earlier age, however, first affecting his locomotion at between the years of twelve and fourteen. It progressed with comparative rapidity, without any tendency to arrest, and finally reduced him to the pitiable state of a paralytic. The upper extremities became involved in a very few years after the initial symptoms, although with awkwardness and much effort he possessed sufficient control over the arms and hands to enable him to indulge in occasional clock repairing, and work of like character. He was of a violent temper,

but his mind was moderately bright, and he possessed considerable mechanical ingenuity. Vision and hearing were apparently good; general health excellent; he was well-nourished, and there was no evidence of any further trouble or derangement, except the progressive paralysis. He died in his twenty-eighth year, at which time he was unable to walk at all, and indeed could not even stand without assistance.

Second Generation.—The oldest sister of these brothers, who was also the eldest child, was always strong and active, and is still living in perfect health. She married Mr. K., a healthy man, and has several daughters and one son.

Case III.—This son began to develop at an early age, about the tenth year, symptoms very similar to those shown by his uncles, namely, unsteady and awkward gait, a want of activity, frequent tripping and stumbling, and fatigue in walking, or after any moderate exertion. These symptoms, however, have not made any decided progress or change in the last few years, and he is now able to follow a non-active avocation.

I did not succeed in making a personal examination of this case, but obtained these data from the family physician.

The most important and interesting cases of the group are the sons of the other sister through whom the heredity was transmitted. This lady was the youngest child; was born prematurely (seventh month), but was healthy and vigorous. At the age of eighteen she married Mr. F., a strong, hearty man, with no hereditary or other history of taint, although he indulged afterward for many years in strong drink, then reformed, and is now a religious enthusiast. It should be mentioned, also, that she became addicted to the use of both alcohol and opium. Her husband states that she was a strong, hale, vigorous woman, but was clumsy, slow, and awkward in her movements, and had noticeably long limbs.

She gave birth to sixteen living children at term —six sons and ten daughters—and two miscarriages, and died of uterine cancer when forty-nine years old. Of these children, one daughter died at sixteen years of age of typhoid fever; another daughter fell a victim to smallpox in her eighth year, and five others succumbed in early infancy to intestinal disorders. Three of the sons also perished in infancy from enteric troubles, being bottle-fed, but were well formed and vigorous children. Consequently, there are now living three daughters, who are in vigorous health, and three sons, all of whom are the subject of the affection under consideration, and whose histories are detailed below.

Case IV.—Willis, male, brunette, height five feet six inches, was the eldest child, and born in 1855. His birth was perfectly normal; was suckled at the breast, and grew up a healthy, active, and vigorous child until between the years of ten and twelve, at which age he began to lose his activity, and his gait was noticed to be awkward, uncertain, and unsteady. This was soon accompanied by frequent stumbling, the smallest obstacle serving to occasion him a fall, together with great muscular weakness, and fatigue in walking. As the trouble progressed these difficulties increased, and, in addition, especial trouble was experienced in rising from the sitting or recumbent position; and then, when his feet were gained, he was able, with a separation of his legs and the support of a cane, to maintain the upright attitude, and walk in the shuffling, ungainly manner above mentioned. He complained of particular weakness in the legs, and in walking the feet were stamped, or placed "flat" on the ground, and dragged the toes in lifting them for a step. All movements were slow and deliberate, with an air of hesitation and uncertainty about them. Mind dull, but no actual mental deficiency, and disposition gentle and patient. Arms first showed involvement about seven years ago.

The malady has steadily progressed until when I first saw him (1885) he was unable to rise from his chair, and could not stand unless firmly supported. The upper limbs were likewise almost useless; his grasp was exceedingly feeble; there was inability to handle easily small objects, and in placing the finger on the nose, or carrying a glass of water to the mouth, the arm was slowly and tremblingly brought around in a wide circle, and supported near the wrist by the opposite hand. The entire muscular system was wasted and flabby, but the thighs and arms, in comparison with the forearms and calves of legs, notably so. When the leg was crossed "foot-drop" was marked. There were no contractures, no joint or bone changes; action of sphincters sufficient; taste natural and digestion good, with the exception of constipation. Both hearing and vision apparently normal, and ocular movements natural. Knee-jerk abolished on both sides. There had never been either pain, anæsthesia, or numbness, and the tongue was protruded slowly but without tremor.

He had always enjoyed excellent health, and never suffered from any illness, except once about ten years ago. This attack was of a tetanoid character, and bore a striking resemblance to chronic tetanus, first affecting the muscles of the neck, and then those of the shoulders and arms, and lasting, notwithstanding medical treatment, several weeks. This then gradually subsided, leaving all the limbs, especially the upper, weaker, and with less coördination.

In the last few years his intellect had grown somewhat impaired, and now his speech was slow and hesitating. He remained in about this condition until September, 1886, when he contracted a slight cough. This continued for a day or two without any other observable symptom, when suddenly he became comatose, with dilated pupils; cyanotic; rapid, shallow respiration; small, wiry pulse; complete abolition of sensation and all reflex action, except slight effort to cough, and died after an illness of sixteen hours.

No post-mortem permitted.

Case V.—Ervin, the third child, was born in 1860. He was a strong, vigorous infant; reared by a wet-nurse, and remained healthy and active until ten years old, when the first nervous symptoms were observed. These were very similar to, and progressed exactly like, those with his older brother, namely, unsteady and awkward gait, frequent stumb-

ling, fatigue in walking, and general lack of power in and control over the legs. This incoördination has advanced slowly up to the present time, when my examination now shows his condition to be as follows:

Aged twenty-eight, height five feet two inches, decided blond, rather small frame, square shoulders, and when dressed his chest appears large for the rest of his body. Head large and symmetrical; face well-featured and intelligent. Speech naturally quick and without hesitation. Appearance of face indicates moderately good nutrition, but palpation shows muscular wasting. This is decided over scapular regions, arms, and thighs; but the muscular groups forming the calves of legs and forearms, although not normally full developed, are much larger and firmer in proportion than the thighs and arms. Abdominal muscles also large. Marked antero-posterior with slight lateral curvature of spine—a line dropping from the seventh cervical vertebra falls wide of the sacrum. No osseous lesion, hence curvature is evidently muscular. When erect this gives him a "sway-back" appearance. No trophic disturbances—joints and bones normal.

Locomotion is effected in a winding, shuffling manner, with the feet rather widely separated, and aided by a cane: the body is bent backward, legs separated so as to widen his base, and the feet lifted and swingingly placed on the ground, with a dropping of the toes. The cane held in the right hand is placed somewhat in the rear of the body. The gait, however, is not typically ataxic, the weight of the body seems to be borne rather on the ball of the foot than on the heel, or entire foot, and is characterized as much by a want of power as lack of control, although incoördination is quite marked. He declares that walking is not especially fatiguing, but he evidently remains standing as much as possible to avoid rising and sitting down. Rising from the sitting posture is markedly difficult and awkward, and is accomplished in this wise: First the chair which he occupies is pushed back to the wall so as to gain a *point d' appui*, then the feet are widely separated, and with the hands supporting the body by resting on the knees, the body in this bent-over-attitude is thrown forward to a chair opposite, which is then seized and the body pulled up in a sort of climbing fashion. The act of sitting down is not so laborious, and is accomplished by an awkward side motion—standing at the side of the chair with the hands resting on the knees, and dropping into the seat sideways.

The use of his arms is also very awkward and uncertain. When carrying the hand to the mouth he first raises the elbow from the side, and then in a circling manner advances the hand to the face. He has some skill, however, in the use of his fingers (forearm muscles)—writes a good hand and is a fair draughtsman. When he crosses his knees he has to lift the leg by means of both hands over its fellow. Knee-jerk absent, and grasp feeble. Tarsal arch somewhat exaggerated, and great toes inclining upward, showing slight contracture. When standing with eyes closed and feet close together there is some swaying (Romberg symptom), but he does not fall, although he is timid about this position. Says he has no particular difficulty in walking in the dark. But with the eyes open he stands without oscillation. However, he is so uncertain and tottering on his feet that when not on his guard the slightest jostle will cause a fall. There is no pain of any sort and has never been. No numbness or localized anæsthesia; and no cramps. Sexual ability said to be moderate. Never suffered from any serious illness. Hearing acute and taste normal. Ocular muscles strong and coördinate. No nystagmus. Pupillary reflexes present (no Argyll-Robertson symptom).

O. D. V $= \frac{12}{XII}$.

O. S. V $= \frac{12}{XII}$.

F. normal. Reads J. I. Chromatic sense undisturbed (Holmgren's test).

Ophthalmoscope (without mydriasis) shows in Oc. Dex. clear media. Refraction H. Disk round, clearly defined, slightly whitened or rather grayish at temporal side, but otherwise well-nourished. Retinal vessels natural in size, course, and color. No striations and no splotches. Macula normal.

Oc. Sin. about as on the right side. Media clear. Temporal side of disk perhaps slightly more gray or whitened. Vessels, retina, and macular region normal. Refraction H.

No electrical examination made. His father recognizes a gradual increase in the progress of the malady.

Case VI.—Abraham is the eighth child; born in 1870, and is consequently seventeen years of age. He was bottle-fed, but thrived on artificial food, and until eight years old was as healthy, active, robust, and bright a boy as could be found. At this period, however, the approach of nervous trouble became manifest. This, as with his two older brothers, was first evidenced in his gait—consisting in an unsteady, awkward, and staggering walk, associated with fatigue. These symptoms have gradually become more pronounced, advancing upward, and the implication of his arms dates back about five years.

Present condition (April, 1887): Height, five feet four inches; complexion dark; of rather slender build, but moderately well nourished; limbs disproportionately long; thighs, shoulders, and arms small, but muscles not atrophic. On the other hand, forearms and calves of legs of good size and firm. Grasp very feeble. Of ordinary intelligence, but speech not especially quick. No arthropathic changes. Decided antero-posterior spinal curvature (muscular)—a line from the neck falling outside of sacrum. This appearance of "sway-back" is very marked when he walks. Thorax asymmetrical—right side flattened anteriorly and bulging posteriorly and laterally—but no vertebral disease. Foot well arched, perhaps exaggerated, but no contractures. Neither pain, anæsthetic areas, numbness, nor cramps. Gait staggering, unsteady, and incoördinate—walking in a sort of rocking way, and slinging legs along—and stumbles easily. But it is

much more sure and steady than in the case of his brother. He is able to cross his legs without the assistance of his hands, but he slings them over as if they were dead weight. "Foot-drop" marked. Patella reflex scarcely demonstrable. Standing still with eyes closed and feet together is easily accomplished, but body sways both backward and forward and laterally. No oscillation with eyes open. No difficulty in walking in the dark, except the necessary precaution respecting obstacles, which readily cause stumbling. Walking does not induce marked fatigue. Tongue steady and not ataxic. Hearing and taste normal. Action of the sphincters natural. Rising to erect posture and sitting down are accomplished exactly like the same movements by his brother (Case V.), only to a much less degree. He is able to rise by separating his feet, bending his body forward, at the same time supporting it by his hands resting on his knees, and then by a sudden movement, or rather a jerk, of the body forward, he staggers to his feet. Sitting down is done in the side-way fashion as described in his brother's case. Uses hands with apparent ease and facility, and writes a very good but stiff hand. An attempt, however, to carry his hand to his face, although readily done, is awkwardly executed, the same abduction of the elbow and circling motion of the hand being employed. In a word, all the symptoms are exactly those manifested by his brother (Case V.), the only difference being one of degree, and, therefore, are not so pronounced.

O. D. V = $\frac{12}{xv}$.

O. S. V = $\frac{12}{xv}$.

Irides bluish-gray. F. narrowed. Pupils somewhat dilated, and react feebly to light. Accommodation paretic. Reads J. I, with + glass. Extra ocular movements normal. Chromatic sense natural (Holmgren's test).

Ophthalmoscopic examination without mydriasis. O. D. clear media. Macular region normal. Papilla round, grayish, especially temporal side, with obscure edges and slight retinal striations radiating therefrom, and deep physiological cup. Vessels normal in size, course, etc., after leaving disk. Refraction H.

O. S. condition quite similar to right eye. Disk round, grayish-white, moderately clearly defined, and fine retinal striations. Physiological cup. Media and macula normal. Refraction H.

No electrical examination made. The patient believes that there has been no increase in his symptoms in the last two years, but his father notes a gradual but decided progress.

It is not my intention to discuss the theories involved in congenital ataxia. The subject has received already careful consideration at competent hands; and besides, having in view only a clinical report, it will be unnecessary to examine critically the various symptoms which it presents, either in common with or dissimilar to those of the general form of posterior spinal sclerosis. I do desire, however, to give greater prominence to the special features of the present cases than the mere detail of their histories permits, and to this end will pass in review the several points of interest which they offer.

Among those deserving of mention are:

1. The positive history of transmission which establishes their claim to the title of hereditary ataxia. It is essential that the element of heredity should be distinctly indicated in all these cases of so-called Friedreich's disease; but in the majority of the recorded examples this characteristic is absent or, at least, not clearly traced. They are described rather as occurring in families of the same generation, and, therefore, would be more properly termed family ataxia, or congenital, or perhaps early ataxia. Even the now classic cases of Friedreich are not hereditary, but really belong to the family class. Our own cases, however, are well defined. In them the evidence of transmission is prominent, the affection being clearly conveyed from one generation to another, and including three separate families of children. The absence of this necessary hereditary feature in many instances, would suggest the name *family* ataxia as the most appropriate and descriptive designation to embrace the whole class of this division of ataxia.

2. The affinity manifested by the disease for the male line. It is interesting to note that of the six cases all were males, and this, too, notwithstanding the fact that in each of the branches in which they occurred there was a large number of female children (five daughters in one, four in the second, and ten in the third), but in no instance were the girls affected. Furthermore, the transmission was not directly through the afflicted persons, but took place through two sisters—cropping out in their sons. This is not in accordance with the recent statistics of the disease, which, I believe, point to the female line as most frequently affected.

3. The attacking of *all* the males of the two generations who passed beyond the stage of infancy.

In the first generation there were two sons, and both were ataxic; in one branch of the second generation there was only one son, and he became affected, and in the other branch there were six sons, three of whom were paralytic, the other three, however, dying in early infancy, before reaching what might be called the ataxic period.

4. The steady and uninterrupted progress of the disease. There were no lulls or stationary intervals in the course of the malady, but, on the other hand, its march was even and unbroken. Each month and year brought a definite increase of the symptoms until the affection had attained its height and death terminated it. In the cases living (excepting Case III.) this regular advance is still in progress—the disease now passing through the same characteristic and uninterrupted stages.

5. The identity of the symptoms. The peculiar uniformity in the symptoms presented by each of the cases should not escape mention. Of course, the main features of the disease were necessarily alike, but, in addition, the less important manifestations were so exactly the counterpart of each other that a detailed description of one case would almost suffice for all.

6. The apparently definite duration of the disease.

In Case I., ataxic symptoms were first noticed at the age of fifteen, death occurring in his thirty-first year—a period of a little over fifteen years; in Case II., the disease appeared between the years of twelve and fourteen, and death resulted when twenty-eight years old—also a space of about fifteen years. In Case IV., invasion occurred at the age of between ten and twelve years, thus lasting about sixteen years. Cases III., V., and VI., are still living, their ages being twenty-seven, twenty-eight, and seventeen years respectively, in none of whom has the disease yet reached the length of what, in these cases, would appear to be the average duration of the malady.

7. The comparative rapidity with which the disease spread upward, implicating the arms and superior portions of the body.

This feature is noteworthy in that it is at variance with the usual progress of the ordinary or Duchenne variety of ataxia. In the latter the invasion of the upper extremities is decidedly slow, and, in many instances, they even escape all involvement. In all of the present cases, however, the arms became early and rapidly affected.

8. The ages. Friedreich declared that its appearance was concurrent with the approach of pubescence, but many recorded instances have demonstrated such to be a mistaken belief. In our cases, puberty was certainly neared; the earliest notice of appearance was the eighth year, the others occurring between the ages of ten and fifteen.

9. The absence of pain and other sensory disturbances. This is well exemplified here, being also one of the important and distinctive features of family ataxia, in contradistinction to the invariable presence of the lightning pains and certain other sensory phenomena in regular locomotor ataxia.

10. Spinal curvature was an early and positive symptom in Cases III., IV., V., and, from the description obtained, was doubtless equally so in the other two. Spinal curvature is a frequent associate of this type, and it has been stated that the lateral bend is more often encountered, although the combined lateral and angular is not infrequent. In three of our cases the angular curve was alone present, and in one there was a combination of the angular and lateral. In the other two (Cases I. and II.) antero-posterior curvature probably existed.

11. The moderate wasting of the calf and forearm muscles was well marked. There was, of course, decided nutritional changes in these muscular groups, but, in comparison with those of the thighs, arms and shoulders, the atrophy was noticeably less. I have not seen any reference to this feature elsewhere, but in the present case it was sufficiently marked to furnish ground for comment.

12. In the cases personally examined by me there were no extra-ocular disturbances, and none were apparent to the ordinary observer in the other cases of the group.

Intraocular lesions were undoubted, however, in two cases, and in one of these there was also slight mydriasis, with cycloplegia.

13. The marriage of blood relations. This is not the place to discuss what effects may be entailed upon the offspring resulting from consanguineous unions, or, if such result, the character of these influences. It is only necessary to refer to the fact that, in the present instance, first cousins married. These persons were both vigorous and healthy, and, as far as known, possessed a family history free from all nervous or other troubles. Therefore, it is justifiable, at least, to consider that with this union were brought together or originated those causes which produced the disease, since it was manifested in a progressive and uniform manner in the two succeeding generations.

REPORT OF A TOXICOLOGICAL EXAMINATION OF FIVE BODIES IN CASES OF SUSPECTED SATURNINE POISONING BY LEAD CHROMATE.

BY JOHN J. REESE, M.D.,
PROFESSOR OF MEDICAL JURISPRUDENCE AND TOXICOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

Within the past few months this community has been thoroughly aroused by the discovery of the very extended adulteration of buns and other cakes by certain bakers in the northern section of the city with *lead chromate* (the *chrome yellow* of painters), as a cheap substitute for eggs, on account of the yellow color thereby imparted to the dough. Quite a number of persons have been fatally poisoned through this practice, whilst many others have been seriously affected; and all have exhibited, more or less, the characteristic symptoms of chronic lead poisoning—such as abdominal pains of greater or less severity, nausea, vomiting of greenish-yellow matters, obstinate constipation, pains in the joints, limbs, and head, furred tongue, fetid breath; and in many of the cases severe convulsions, which appeared to be the immediate cause of death. The characteristic blue line at the junction of the teeth and gums was observed in several of the cases, both fatal and non-fatal. A somewhat singular fact relating to the fatal cases is that none of them exhibited signs of paralysis—especially of the extensor muscles of the hands, constituting the well-known *wrist-drop;* whilst, on the other hand, the eclamptic symptoms were more pronounced than is usual.

In one single family—that of the very baker who employed this poisonous adulteration most extensively in his business, and whose "buns" were the means of dealing out death to many others—no less than seven members were affected, all of them fatally. In another neighboring family of nine persons, six had eclamptic attacks, four of whom died.

This system of wholesale poisoning seems to have been going on quite unsuspectedly for some years in that particular section of the city; though subsequently, it has transpired that other districts have been similarly affected. One member after another of a family would fall sick, languish for a longer or shorter period, and finally die. And inasmuch as the convulsions constituted such a prominent symptom—these often coming on suddenly and unexpectedly,—the attending physicians appear very naturally to have been mistaken in their diagnosis, and the unfortunate sufferers were treated for other supposed disorders. Finally, however, in one of the

families above mentioned, after the death of two of the children, Dr. David D. Stewart was called in to visit a third child, fifteen months old, who like the preceding ones, had been suffering from a mild attack of pertussis. This child had a number of convulsions for several successive days, but he finally made a good recovery.

Within a few weeks another child, aged seven and a half years, after some slight general ailing, was suddenly, and without premonition, seized with severe general convulsions, which shortly terminated in coma and death. Dr. Stewart did not see this patient until some time after the first convulsive seizure, and at that time could have no suspicion as to the true origin of these attacks. Four other members of this family were subsequently attacked with similar symptoms—one, a girl of twelve years, fatally, the death being preceded by intense headache and severe continued convulsions.

Very naturally, such a continued series of cases, occurring in the same family, and presenting such similarity of symptoms, led the physician to suspect some other cause than the mere supposed digestive disorder, or the early whooping-cough, to account for these violent and fatal seizures; and by prompt and skilful investigation he was enabled to trace them to their true origin—*saturnine poisoning*, derived through the continued use of "tea" and "cinnamon buns," which had been procured from a neighboring baker, who was in the habit of adulterating his dough with lead chromate as a cheap coloring substitute for eggs!

Dr. Stewart further discovered that this same baker had within the past two years lost a wife and six children in convulsions, and that lead-poisoning had been suspected to be the cause of death in most of these cases; and further, that a journeyman baker in his employ had been seized with lead colic, and been forced to leave him.

Singular to say, although the circumstances attending these different cases were so peculiar and suggestive, the true cause of all this wholesale poisoning was never discovered until Dr. Stewart's thorough investigation revealed it (see THE MEDICAL NEWS of June 18, 1887, p. 676). He took some of the suspicious yellow coloring matter to his friend, Dr. Leffmann, who at once pronounced it to be lead chromate; and who subsequently detected the poison in samples of the "buns" sent to him for analysis.

The matter now fell into the hands of the Coroner. Some autopsies of the bodies had been previously made at different times by the Coroner's physician; but in the absence of any suspicion of lead-poisoning, the mere post-mortem could not, of course, reveal the true cause of death. This officer at once commenced a thorough and elaborate investigation. Four of the bodies of the victims were disinterred. Two of these had been buried about two years; one about five months; and one a little over one month. As analyst to the Coroner, it became my duty to make the toxicological examination of these cases, with the view of discovering the presence of the suspected lead in the remains. Dr. Henry Leffmann, Port Physician of Philadelphia, who had previously analyzed the colored matter found at the baker's, and also some of his buns, was associated with me in this investigation. We made our experiments upon the different viscera conjointly, and always in each other's presence, so as to be able to substantiate the results in every instance. Some of these viscera were in a highly putrescent condition, but were still capable of proper manipulation.

The process adopted by us was the following: The organ to be examined was first divided into fragments and carefully dried by exposure to heat—a process often requiring many hours to accomplish. It was next heated to full redness in a porcelain capsule over a gas-furnace, until it was completely incinerated. This process also was very tedious, often consuming considerable time, and even then, not always attaining the desired end. We found it generally necessary to make several successive additions of small quantities of nitric acid, for the purpose of effecting the more complete destruction of the organic matter. In fact, we ascertained that in a lead-analysis of this character (and the same is doubtless true of copper and other non-volatile metals) it is not sufficient merely to carbonize the material, however thoroughly this is done; but the carbon must be completely reduced to ash, in order to separate the contained metal by subsequent solution in dilute nitric acid. As has been previously pointed out by others, we found that the animal charcoal, under these circumstances, retains the lead with great tenacity, refusing to part with it even when heated in the acid solution. So that, unless special care is exercised by the chemist to insure the *thorough* incineration of this carbonaceous matter, he may entirely fail to recover the poison sought for. As already remarked, this complete incineration required a long and tedious attention on the part of the analyst.

The ash thus obtained was next dissolved in dilute nitric acid at a moderate heat; filtered, evaporated to dryness, and again dissolved in distilled water; it was now ready for the different tests for lead, which gave us the following results:

(1) *Sulphuretted hydrogen* threw down a black precipitate (lead sulphide); this was further corroborated by dissolving the precipitate in dilute nitric acid by the aid of heat; evaporating to dryness; again dissolving in distilled water, and testing the solution by some of the other appropriate reagents, which yielded satisfactory results.

(2) *Dilute sulphuric acid* yielded a white precipitate (lead sulphate), soluble in larger excess of potassic hydrate.

(3) *Potassic hydrate* threw down the white hydrated lead oxide, soluble in an excess of the reagent.

(4) *Potassium iodide* gave the characteristic precipitate of the yellow iodide of lead. This was further corroborated by its solubility in hot water, and by the distinctive six-sided crystalline plates, as seen under the microscope.

(5) *Potassium bichromate* yielded the yellow precipitate of lead chromate.

(6) A fragment of pure metallic *zinc* placed in the solution was speedily coated with bluish colored crystals of metallic lead.

There are a few other tests of minor importance, which we did not deem it necessary to employ.

The following are the actual results of our experiments upon the different viscera submitted to analysis:

Case I.—Amelia D., aged twelve years. Health failing since the beginning of the present year, but only decidedly ill for a few days before death, on May 13th. The only organs submitted to us were a small portion of the upper part of the spinal cord, a kidney, the heart, and the lower jaw. The fragment of the *spinal marrow* (about nine inches in length) examined in the manner above described, yielded traces of lead to several tests. The *kidney* also afforded evidences of its presence by the sulphuretted hydrogen and zinc tests. The *heart* gave no appreciable results; and the same is true of the *lower jaw*. Unfortunately, in this case the stomach and liver had been previously removed.

Case II.—Louisa D., sister of the preceding, aged three and one-quarter years. Had a mild attack of pertussis since January; became seriously ill about January 23d, with vomiting; died in convulsions on January 24th. The viscera submitted to examination were the stomach, with a small portion of the small intestine, one-quarter of the brain, one-quarter of the liver. The *stomach* and fragment of *intestine*, treated as above, yielded evidence of the presence of lead by the sulphuretted hydrogen (corroborated subsequently) and the zinc tests. The portion of the *liver* gave decided results with the sulphuric acid, sulphuretted hydrogen, potassium iodide, potassa and zinc tests. The portion of *brain* afforded us slight, though unequivocal evidence of the presence of lead in this organ, especially by the sulphuretted hydrogen test, subsequently corroborated.

Case III.—George P., aged twenty-four years, died January 23, 1886, in the Philadelphia Hospital after (as was supposed) an epileptic seizure. This was one of the children of the baker above alluded to. The *liver*, which had been well preserved in alcohol, was treated as above mentioned, and afforded most decided evidences of the presence of lead when subjected to the sulphuric acid, sulphuretted hydrogen (corroborated), iodide of potassium, hydrate of potash, and zinc tests.

Case IV.—E. L. P., sister of the preceding, aged twenty years, died December 13, 1885. A portion of the *liver* (one-quarter) was treated according to the before-mentioned method, and yielded on the first incineration no evidence of lead, but only a considerable quantity of oxide of iron. The result of a second and more perfect incineration indicated a slight trace of lead; and one *kidney*, treated as above, yielded very positive indications of lead by means of the sulphuretted hydrogen, potassium iodide, and sulphuric acid tests.

Case V.—Besides the above four cases of the disinterred bodies, there were also submitted to us for analysis some of the viscera of the child A. E. H., aged six and one-half years, who had died quite recently (June 25th) after partaking of "buns" purchased from another baker living over a mile distant from the former one. One-quarter of the liver and spleen were examined together, and the ultimate solution afforded us very positive proofs of the presence of lead in these viscera, when subjected to the above-mentioned tests, especially sulphuretted hydrogen, potassium iodide, and sulphuric acid.

The point of most interest in the above cases—physiologically and toxicologically considered—is probably the fact of the detection of lead after death in the two great nervous centres, the brain and spinal cord.

It has been asserted by some who have experimented with this poisonous metal on the lower animals, that it has a special affinity for these organs, and that it was found after death in them in greater abundance than even in the liver. The results of our experiments upon the human subject, as above detailed, do not confirm this statement, but, on the contrary, show that the liver, as a general rule, contains more of the absorbed poison than any of the other viscera; and they point to this gland as the great eliminating organ for poisons from the human body.

It is to be regretted that no opportunity was afforded us for testing the urine in any of these cases. Unfortunately, no test of this secretion was made during life. Doubtless, if it had been done, evidence of the presence of the poisonous metal would have been detected. The examination of the urine should never be neglected during life in a case of suspected mineral poisoning, since its presence in this secretion may almost certainly be discovered, in a genuine case, by the appropriate chemical tests.

INFLUENCE OF TROPIN HYDROCHLORATE AND SODIUM TROPATE ON THE BLOOD-VESSELS OF THE DOG,

ACCORDING TO AN IMPROVED METHOD.

By H. G. BEYER, M.D., Ph. D.,

passed assistant surgeon, U. S. N., fellow by courtesy of the Johns Hopkins University.

By a careful, experimental study of atropine on isolated organs, we have been able to furnish good pharmacological evidence in proof of the fact that this alkaloid exerts a double action on those organs which are supplied by both motor and inhibitory sympathetic nerve-structures. It has been shown that very small doses of the drug will stimulate the motor nerve-elements, and that large doses of it will stimulate the inhibitory portion of the nerve-supply of these organs.

Thus, very small doses of atropine give rise to contraction of the pupil, to acceleration of the heart's action, and to increased peristalsis of the intestine; large doses, on the contrary, produce dilatation of the pupil, arrest the heart in diastole, and stop the peristaltic movements of the intestine.

In view of the researches of Ladenburg, on the chemical constitution of atropine, it seemed to me very desirable to try and ascertain if this double action of atropine could possibly be explained by a careful study and comparison of the action of its two constituents, *tropin* and *tropic acid*.

It will here be necessary to recall briefly a few of the more essential points of interest as regards the chemistry of atropine.

Some years ago, Kraut and Lossen succeeded in splitting up the alkaloid atropine into its two constituent molecules. Lossen, more especially, succeeded in showing that the decomposition mentioned went on according to the following equation: $C_{17}H_{23}NO_3 + H_2O = C_8H_{15}NOC_9 + H_{10}O_4$. Finally, Ladenburg, in 1881, produced atropine by synthesis from tropin and tropic acid, by first neutralizing a solution of tropic acid with tropin, thus producing tropin-tropate; then boiling this compound with a small quantity of HCl in a sealed tube.

The result of this procedure was a substance absolutely identical with atropine obtained in the natural way from the plant, in all its chemical and physiological properties. The chemical identity of this substance was established by Ladenburg himself; the physiological experiments necessary were made by Professors Hensen, Völkers, and Falck.

According to the same method, Ladenburg now undertook the manufacture of certain other substances to which he gave the name of *tropeïnes*, but which are in reality atropines in which the tropic acid molecule was replaced by a molecule of some other suitable acid. Many of these so-called tropeïnes were in this manner produced, but the consideration of a few will perhaps suffice for our purpose. (1) Homatropine is one of the best known tropeïnes, and in it tropic acid has been replaced by amygdalic acid; one of the chief characteristics by which it may be distinguished from atropine is its effect on the pupil, which is much less permanent, though equally as pronounced as, in the case of atropine. (2) Salicyltropeïne, made, as its name implies, by substituting tropic acid by salicylic acid, has, according to experiments made by Prof. Falck, no effect whatever on the pupil; it is said to be a weak poison, affecting especially rabbits very slightly indeed. (3) Oxybenzoyltropeïne has a certain effect on the pupil, lasting, however, but a very short time, and its action is much less pronounced than that of atropine, according to experiments made by Prof. Völkers. (4) Cinnamyltropeïne, made by substituting tropic acid by cinnamic acid, while it was found to be a strong poison, $\frac{1}{12}$ a grain killing a frog in three minutes, had no appreciable effect on the pupil whatever. It will be seen, then, that with the replacement of the tropic acid molecule in atropine by a molecule of other acids, a very decided modification in its effects on the pupil is thus produced, and the inference, therefore, was quite a natural one, that there exists a certain definite physiological relation between this molecule and the dilatation of the pupil.

Active dilatation of the pupil, however, is produced by the stimulation of certain nerve-structures, belonging, according to Gaskell, to the class of inhibitory nerves, considered both physiologically as well as histologically.

From the results I obtained in some investigations on the direct action of the members of the atropine group on the heart and bloodvessels, I was led to believe that they all exhibited a stimulatory influence on both inhibitory and motor nerve-structures. It was found that the administration of small doses of atropine was accompanied by phenomena indicative of vasomotor nerve-stimulation, and that of larger doses by phenomena indicative of inhibitory nerve-stimulation. These results, as well as those obtained by Professors Hensen, Falck, and Völkers, suggested to me the possibility of finding an explanation for this double action of atropine in a further study of the action of its two constituents, tropin and tropic acid.

The pupil did not seem to me a sufficiently typical object for the determination of this all-important point, and I, therefore, concluded to try the bloodvessels, which seemed to me particularly well adapted to this end, since it is now looked upon generally as a well settled question in physiology that they are supplied by two kinds of sympathetic nerve-structures, namely, vaso-motor and vaso-inhibitory, the stimulation of the former causing vaso-constriction, that of the latter giving rise to vaso dilatation.

From what has been said so far, we may argue that if tropic acid is that part of atropine which causes pupillary dilatation, and if we have, furthermore, reasons to believe that tissues which are identical, both in histological structure and physiological function, are also similarly affected by the same chemical stimuli, then certainly it ought to follow that this same part of the atropine molecule should give rise to vaso-dilatation. Atropine, however, producing also vaso-constriction, in certain doses at least, it would perhaps further follow that the remaining portion of the molecule should give rise to vaso-constriction.

It is plain that for the purpose of deciding so very delicate and important a question, the employment of the best available method of experimentation was necessary. That employed by Prof. R. Kobert, in his experiments "on the Influence of Pharmacological Agents on the Bloodvessels," as published in the *Therapeutic Gazette* for January, 1887, is briefly as follows:

The particular organ under experimentation (in most instances the kidney) was removed from the body of the animal, kept at the proper temperature by means of a properly constructed heat-chamber, and provided with the necessary canulas for transfusion experiments. The blood, always coming from the same animal or another one of the same species, was likewise kept at the animal's temperature by the same means; it was then arterialized by shaking it in a bottle containing air, and made to flow from Mariotte's flasks from a height corresponding to the normal arterial pressure of the animal during life. After the flow of blood through the organ had become uniform, poisoned blood was substituted for normal blood, and the condition of the vessels simply inferred from the change which took place in the outflow.

Most valuable results, no doubt, are obtained by means of this method, but still there are certain objections clinging to it which are as undeniable as they are difficult to remove. The latest achievement as regards improvement in method has been effected by Drs. von Frey and Gruber. (*Du Bois-Reymond's Archiv*, 1885, pp. 519–533.)

In Kobert's experiments, as mentioned above, the blood was arterialized by shaking it in vessels containing air, and its flow through the bloodvessels was uniform and uninterrupted.

It has been found that under these conditions, the blood corpuscles tend to settle and clog up the finer capillaries, and the blood, as it becomes more and more venous by standing, gives rise to contraction of the arterioles and capillaries, and, therefore, the necessity of gradually increasing the arterial pressure as the experiment proceeds, in order to maintain a uniform flow through the bloodvessels may be sufficiently accounted for by these two conditions.

In order to overcome these difficulties, von Frey and Gruber constructed an apparatus intended to establish a uniform and steady arterialization of the blood on the one hand and a flow of blood on the other, which would be more like that occurring in the normal intact animal. For the purpose of arterializing the blood, the apparatus was so arranged as to allow the blood to be spread out in thin layers over the walls of glass vessels containing air, from which it could take up any desirable quantity of oxygen and give off a corresponding amount of carbon dioxide. The blood thus arterialized, was collected and forced into the bloodvessels by means of a pressure and suction-pump, which was so arranged that when at work it somewhat resembled the heart's action. In other words, an ingenious attempt has been made by von Frey and Gruber to overcome the objections adherent to the old method by means of an artificial heart and an artificial lung.

In the method made use of in the experiments to be here described, a *natural heart and lung* were interposed between the blood reservoirs and the bloodvessels of the organ under observation, the arrangement being very simple and briefly as follows: The operation consisted in first isolating the heart and lungs of a dog and placing them in proper working order exactly as was described in connection with some experiments on the isolated heart published in the *American Journal of the Medical Sciences* for April, 1887. The outflow-tube, however, had a T piece inserted into it, close to its origin from the common carotids; two branches of this T piece being of course in the tube, the third branch was connected with the femoral artery by means of a rubber tube and glass canula of about the diameter of that artery.

The pressure against which the heart pumped its blood being made equal to that of the animal during life, that of the femoral artery under these conditions was exactly the same, as was ascertained by a mercury manometer, and pulsations could be distinctly felt in the limb.

Everything being arranged in good working order, a constant and uniform flow of blood through the limb was soon established; the blood being collected from the femoral vein and measured at stated intervals. The vena cava inferior, furthermore, having been previously tied above the liver when the heart was isolated, any loss of blood was prevented and only that portion of the limb was kept in circulation which corresponded to the area of distribution of the common femoral artery.

After the amount of outflow had become uniform, the drug was slowly injected into the femoral artery, and the condition of the vessels simply inferred from the change which took place in the outflow during and immediately after the injection was made.

The advantages of this method over the old, must, I think, be quite apparent to any one. Every drop of blood which flows through the organ is in the first place arterialized by the natural lung of the animal, exactly as it is under normal conditions, and besides, being pumped into the bloodvessels by the heart of the same animal, it really enters and flows through the vessels under the same conditions which prevail in the normal intact animal during life. Furthermore, the drug not being allowed to flow through the heart, both its rate and work were not interfered with, but remained uniform as long as the blood was good. The amount of work done by the heart formed an easy guide as to the condition of the blood, and as soon as a decided decrease took place the experiment was at once discontinued.

The drug was invariably dissolved in a small quantity of normal salt solution and injected into the femoral artery by means of a fine hypodermatic syringe, the injection lasting from between 20 to 30 seconds each time. Dog's blood had to be used in every instance, for, although very young sucking calf's blood had been found to enable the heart itself to perform normal work for a short time, it was, on the contrary, found absolutely impossible to obtain a current through the kidney or limb of the dog by means of other than dog's blood.

In the twelve experiments which were made in this manner, in not a single instance did œdema of either lung or limbs occur, which is an almost invariable occurrence when strange blood is used. The quantity of blood, which is generally obtained by bleeding four large-sized dogs, until marked changes in respiratory movements set in, is amply sufficient for an experiment of this kind. Dogs, bled at intervals of two weeks, may thus be used several times.

From our experiments we are justified in drawing the following conclusions, namely:

1. That tropin hydrochlorate gives rise to vaso-constriction by exciting the vaso-constrictors, and 2, that sodium tropate causes vaso dilatation by exciting the vaso-dilator, nerve elements.

On account of the small quantity of these substances at our disposal, no detailed experiments have as yet been made on other organs, but it was found in one instance that a small quantity of sodium tropate introduced into the heart, caused almost instantaneous diastolic arrest of that organ.

In concluding, I have to acknowledge my indebtedness to Mr. Lengfeld[1] for the preparation of the chemicals made use of, and also to Prof. H. Newell Martin, in whose laboratory these experiments were performed.

LARGE TUMOR OF THE RIGHT FRONTAL LOBE WITHOUT THE PRESENCE OF ACTIVE SYMPTOMS.[2]

By G. E. de SCHWEINITZ, M.D.,
OPHTHALMIC SURGEON TO THE CHILDREN'S HOSPITAL, PHILADELPHIA; OPHTHALMOLOGIST TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

JOHN S., aged eight, was admitted to the surgical ward of the Children's Hospital August 31, 1886. The father is living and apparently a perfectly healthy man. From him no history of syphilis could be obtained. The mother died of phthisis. This boy with two others composed the family, one older and one younger, and both healthy children. The patient's illnesses previous to the date of his admis-

[1] Of the Chemical Laboratory at the Johns Hopkins University.

[2] Read before the Philadelphia Pathological Society, May 26, 1887.

sion were measles, whooping cough, and smallpox. Three years ago swelling of the left ankle began, and a few months later of the right elbow. There is no history of injury to account for the joint affections.

His condition on admission was the following: All the superficial lymphatic glands were much enlarged. The right elbow was enormously swollen, tender, and of a dusky red color. Several sinuses opened on the surface and led down to the joint, which was advanced in disease. The left ankle presented the same condition as the elbow. The tarsus was extensively carious, and there was decided acquired talipes varus. The left thumb was swollen, red and tender, and presented the appearances of syphilitic dactylitis. There was a large broken-down area below each axilla. The teeth were irregular and the cutting edges of the central incisors markedly serrated. In October, 1886, Dr. John Ashhurst excised the right elbow-joint and amputated the left thumb. The patient soon recovered sufficiently to be out of bed. In March, 1887, Dr. Samuel Ashhurst made a partial resection of the left tarsus. The child did well until May 14th, and never showed any symptoms of brain disease.

FIG. 1.

Photograph of child showing the diseased ankle, elbow, and thumb, also the broken-down area below the axilla.

On the morning of this date he was unusually irritable, and during the dressing of his foot apparently suffered pain; afterward until 1 o'clock he lay in a stupefied, though not unconscious state. Then, while being helped to a bed-pan, he was seized with a convulsion, which is thus described by the attending nurse. The convulsive movements began on the left side and were most marked in the face, neck, and arm, with later involvement of the chest and leg muscles. The members of the right side were not quiescent, but were convulsively elevated and drawn toward the median line. The eyes and head were violently turned toward the left side. The convulsion lasted three minutes, and after its cessation the following conditions obtained: There was complete right-sided hemiplegia and contractions of the left side with the production of a typical "claw-hand." Attempted movement of the limbs of this side was resisted in every direction. Neither anæsthesia nor hyperæsthesia existed, although apparently sensation was more acute upon the left side. The pupils were dilated unequally, the left measured seven millimetres and the right five millimetres in the presence of candle-light. There was marked conjugated deviation of the head and eyes to the left. A slight lateral nystagmus was occasionally manifest. The respirations varied; at times they were typically Cheyne-Stokes, at other times deep and almost sterterous, and again, short and gasping. The urine was free from albumin and sugar and deposited freely triple phosphate crystals. Numerous convulsions succeeded the first one, which was the most severe. They were observed by Dr. Morris J. Lewis, by the house-surgeon, Dr. Harvey Shoemaker, and by myself as follows:

The convulsions began on the left side with a spasmodic closure of the eyelid and twitching of the face, neck, arm, and leg. The convulsive wave then rapidly passed to the members of the right side, which were in turn convulsed and drawn toward the median line. These convulsions became milder and milder, until before death they consisted simply of twitchings confined to the left side.

On the evening of the day on which these manifestations began I examined the eye-grounds and found double optic neuritis. The edges of the disks were hidden by the swollen retinas, the surfaces of the elevations were gray-white, and there was wide distention of the lymph sheaths. The veins were full and tortuous, and the arteries by comparison small. No hemorrhages were noted. Death took place thirty hours after the first convulsion with no changes in the symptoms detailed, except a gradual failure of the pulse and several hours before death contraction and equalization of pupils to two millimetres.

Autopsy, six hours after death.

Body of an exceedingly wasted male child. General lymphadenoma; in the groin bunches above and below Poupart's ligament. Submaxillary and axillary glands all enlarged, those in right axilla suppurating. Excision of the right elbow-joint and tarsectomy of the left ankle. Enlarged gland just above the head of the left radius; trochlear glands enlarged.

Thorax: Partly calcified and enlarged lymph glands in the anterior mediastinum under the manubrium. Bronchial glands of the posterior mediastinum very large and cheesy, the entire group of bronchial glands presented this condition and scarcely any trace of gland tissue remained. Those most affected lay immediately anterior to the right bronchus. *Lungs:* A few adhesions at the right apex.

Lungs crepitant throughout; at apices a few small nodules, and here and there on the pleural surfaces were scattered fibroid and calcified tubercles. There were *no caseous areas*, except in the right lung, between the middle and upper lobes, a small partly cretaceous and caseous mass. *Pericardium and heart:* Pericardium smooth. Right heart dilated and full of clots, in the left the blood was fluid. All valves normal.

Abdomen: No peritoneal tubercle. *Liver:* Large, firm, the larger vessels distended. No gross changes noted. *Spleen:* Much enlarged, its hilus occupied by four or five caseous lymphatic glands to which was attached the tail of the pancreas. The body of the pancreas was normal. Section showed no tubercles in the pulp of the spleen, which was soft. *Kidneys:* Large, veins full, cortices opaque in places.

Stomach and intestines: Stomach almost empty and mucosa showed no changes. In the ilium several of Peyer's patches swollen and firm, but not distinctly ulcerated. Mesenteric and retroperitoneal glands all enlarged and cheesy.

Brain and membranes: Head large, symmetrical. Skull cap thin. Dura not adherent, smooth and very tense. The convolutions were swollen, sulci narrow. Gray matter not specially congested.

Inspection of the base: The right hemisphere looked larger than the left, particularly the frontal lobe, which, on separation of the longitudinal fissure, projected considerably beyond the median line, depressing the left median convolutions. On the under surface of the right lobe at the anterior part of the inferior frontal convolution there was a grayish white mass, which measured superficially 3 cm. in diameter. The posterior part of the third convolution was soft and œdematous, and this condition existed in a less degree throughout the orbital gyri. On separating the operculum a firm, solid mass existed immediately outside the root of the olfactory nerve at a point corresponding to the junction of the third right with the anterior gyrus of the insula. Further dissection revealed that this mass occupied two or three of the anterior gyri of the insula. The right middle cerebral artery ran over it, and its branches looked smaller than the corresponding ones on the left side.

There was no special matting of the pia over this mass. The optic nerves were firm and there was wide distention of their sheaths behind the globes. The optic tracts were spread as they passed over the crura. Over the pons and medulla the pia was thickened and infiltrated. The cerebellum was removed by cutting through the crura and was normal. The lower part of the *left crus* was in a condition of hemorrhagic infiltration, and there was a hemorrhagic exudate on the posterior end of the *left thalamus*. The pia, as it dipped in here, was matted and infiltrated. Pons and medulla showed no changes. The ventricles and ependymal veins were distended. In the right lateral ventricle a large grayish white mass was apparent, which occupied the head of the caudate nucleus, the body of which was œdematous. This œdematous condition extended to the anterior portion of the thalamus. No other lesions were found.

Dissection of the tumor region: After hardening the right half of the brain in alcohol, a careful dissection of the tumor region was made. The tumor extended from about half an inch of the tip of the

FIG. 2.

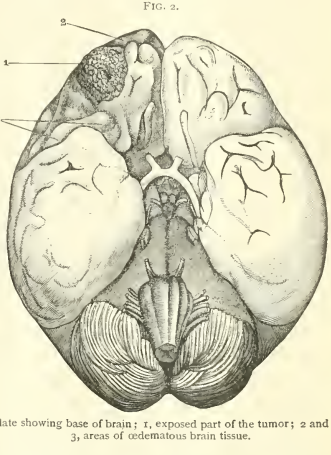

Plate showing base of brain; 1, exposed part of the tumor; 2 and 3, areas of œdematous brain tissue.

frontal lobe to a point corresponding to a section through the bases of the first and second frontal convolutions, about one inch anterior to the fissure of Rolando. Anteriorly it occupied the greater part of the white matter of the lobe, and came to the surface at the junction of the third frontal with the orbital gyri. Its depth was about two and a third inches. It consisted here of two tumors, the larger below, and the smaller above, separated by soft brain tissue. As it passed back it reached the orbital surface, and was apparent immediately behind and external to the root of the olfactory nerve. Its posterior limit was three and a half inches from the tip of the lobe. Section through the prefrontal sulcus showed that here the thalamus and caudate and lenticular nuclei were uninvolved, except one small spot of reddish softening at the top of the lenticular nucleus. The internal capsule was firm and natural. From the ventricular surface the tumor extended to the head of the caudate nucleus, and the parts immediately behind it were softened as far back as the thalamus. Microscopic examination of the tumor showed the presence of tubercle. Attempts to demonstrate tubercle bacilli failed. As before stated, the lesions on the opposite side of the brain were hemorrhagic infiltrations, which occupied the lower divisions (crusta) of the left crus and the posterior end of the left optic thalamus.

REMARKS.—The points of interest in the case which I have just detailed are manifestly the following: A large tumor, 3½ inches long and 2⅓

inches deep, occupied the white matter of the right frontal lobe as far back as the bases of the first and second frontal convolutions, and from the ventricular surface involved the head of the caudate nucleus, and by softening the structures as far back as the thalamus, and yet was practically, if not entirely, quiescent. The convulsions, the hemiplegia, the conjugate deviation of the head and eyes, in fact all the cerebral manifestations that were present during the thirty hours which elapsed between the first convulsion and death, were evidently due to the fresh hemorrhagic lesions in the left crus and on the left optic thalamus. The optic neuritis, on the other hand, must have been present for some time before its discovery, indeed, it was probably the only symptom of the presence of this brain tumor.

The fact that optic neuritis was present in connection with this tumor of the frontal lobe is further interesting, inasmuch as it has been stated that it is just in this region that tumors may exist without the production of changes in the end of the optic papilla. Dr. Gowers has well said, "Morbid appearances in the eye are frequent in intercranial disease, and often prove the existence of such disease when other symptoms are inconclusive, or afford evidence of its nature that can be obtained from no other source." The conjugated deviation of the head and eyes, was in this case as it is in a majority of instances, toward the lesion which produced the symptoms and away from the paralyzed side. The very reverse of this has been noted, and in Prevost's collection of cases, in three such exceptions, the lesion was found in the peduncles of the cerebrum or cerebellum. Here there was a hemorrhagic infiltration into the crus cerebri, but the usual order obtained. This tumor, faithful to its location in the so-called inert zone, produced no symptoms, and was besides too extensive in its invasion of the brain substance to have added any material or accurate data to the knowledge of localization. For the very reason of its quiescence, however, it has seemed to be a useful and interesting case to report, especially in connection with the fresh and active lesions upon the opposite side of the brain.

I am indebted to Dr. John M. Taylor for the drawing of the base of the brain, and to Dr. Randall for the photograph of the child. Dr. William Osler kindly aided in making the autopsy and the subsequent dissection of the brain.

1330 SPRUCE STREET.

THE INFLUENCE OF COCAINE ON THE PUPIL AND CORNEA.[1]

BY EDWARD JACKSON, M.D.,
ADJUNCT PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC.

AFTER a watery solution of cocaine is instilled in the conjunctival sac, there occurs, first, a slight contraction, and then a more pronounced and prolonged dilatation of the pupil. When a drop of the four per cent. solution is used, the contraction comes on with the widening of the palpebral fissure and the anæsthesia of the cornea and conjunctiva, within two or three minutes, and lasts for five or ten minutes, when the pupil resumes its normal size. This contracture, like other delicate reactions of the pupil, is to be satisfactorily observed only by studying the eyes of a young person with equal, mobile pupils, one of which is kept normal as a standard of comparison, while the other is subjected to experiment. And such a study is best made with the accommodation of the observed eye entirely relaxed, and in a rather dim light. These are the conditions, too, that enable one to determine most accurately when the dilatation begins. This is between ten and twenty minutes after the instillation. The maximum of dilatation is reached about the end of the first hour, and an hour later it has sensibly begun to decline; but the return to the normal is not complete for some twelve to twenty-four hours. During the whole period of dilatation the pupil reacts freely to light, often almost as freely as when in the normal condition; and there is almost the usual extent of consensual contraction, with accommodation and convergence. Then, at any time, the dilatation, even that produced by the strongest solutions frequently instilled, may be promptly cut short by the use of eserine.

Frost[1] states that one part of eserine will neutralize twenty-five parts of cocaine in its effect on the pupil. From a series of experiments made upon my own eyes, and those of six other healthy persons varying in age from four to thirty-three years, and unrelated, so that family idiosyncrasy cannot account for the result, I have found that it requires but one part of eserine to overcome the influence of some fifty or sixty parts of cocaine. Strictly speaking, they do not in any proportion exactly neutralize each other. But, when a solution containing one part of eserine to fifty of cocaine is dropped into the eye, there is usually, at the end of fifteen minutes, a slight dilatation of the pupil which lasts but a few minutes, and which may be absent, or may persist rather longer. This is invariably succeeded by a contraction of the pupil, at least when exposed to a good light, which lasts for from one to four hours, and is followed by a normal pupil, or a slightly dilated pupil passing into the normal some hours later.

When, under the influence of these combined drugs, the pupil is about passing from dilatation to contracture, or *vice versa*, and often throughout the whole period of their influence, the pupil subjected to it will contract more strongly than its normal fellow when the eyes are exposed to a bright light, or are strongly accommodated, yet will dilate more widely than the normal in a weak light with the accommodation in abeyance. This illustrates the fact that these two drugs cannot be made to neutralize each other exactly. It might be mentioned in passing, that when the action of eserine on the pupil has been neutralized or overcome by cocaine, its action on the accommodation remains well marked. In every case that could be tested as to this point, in which the mixed solution, eserine sulphate 1,

[1] Read before the College of Physicians of Philadelphia, June, 1886.

[1] American Journal of the Medical Sciences, April, 1887.

cocaine hydrochlorate 50, water 2000, was used, the range of accommodation was markedly extended. In my own case this extension amounted to two dioptres; in another it was fully three dioptres.

Because it leaves the pupil still responsive to light, and its mydriasis is easily overcome by eserine, cocaine is looked upon as a weak mydriatic. Yet with it we may readily attain a perceptibly wider dilatation of the pupil than with homatropia, atropia, duboisia, daturia, or hyoscyamia, either of which can effectually prevent any contraction of the pupil by eserine. My attention was first arrested by this power of cocaine some two years ago; I have tested it very many times since, and have never yet failed to get perceptibly greater dilatation of the pupil with cocaine than with any of the otherwise "stronger" mydriatics. It may be tried in this way: both pupils being under the influence of repeated instillations of a strong solution of another mydriatic and found equal, a drop or two of a four per cent. solution of cocaine is instilled in one eye, and an hour later it is found to present a larger pupil. Or the eye is first subjected to one mydriatic, and the pupil carefully measured; then, after the complete recovery, the second mydriatic is applied, and the pupil again measured. Or, again, one eye, say the right, is subjected to cocaine, while the left is subjected to the other mydriatic, and the pupils compared. After both eyes have fully recovered, the left is subjected to cocaine and the right to the other mydriatic. Of course, when cocaine alone is used, the dilatation is to be measured by a weak light, and while the accommodation and convergence are relaxed. With the other mydriatics it makes no difference whether the light is weak or strong, or the visual axes convergent or parallel.

As examples of this power of cocaine, the diameter of the pupils in the following cases may be cited:

Mrs. J. G., aged fifty, under hyoscyamia, 3.5 mm; cocaine, 5 mm.

Sallie McB., aged sixty, under atropia, 6.5 mm.; cocaine, 7.5 mm.

John F. H., aged forty-two, under duboisia, 4.5 mm.; cocaine, 6 mm.

Samuel E., aged twenty, under homatropia, 7 mm.; cocaine, 8.5 mm.

Edward J., aged thirty-one, under daturia, 8 mm.; cocaine, 8.5 mm.

The wider dilatation by cocaine was well marked in a case of locomotor ataxy, with Argyll-Robertson pupils, which, under cocaine, remained fixed to light, but contracted slightly with convergence. It has been most striking in elderly persons whose pupils would not dilate much for other mydriatics; but is often very considerable in young persons with quite dilatable pupils, as in Samuel E. mentioned above. The mydriatic power of cocaine is, in my experience, quite as constant as that of any other drug if the pupil be examined by a feeble light. And I cannot but think that its supposed inconstancy, spoken of by other observers, was mainly due to variations in degree of light and in the physiological reflex to it.

For diagnostic uses cocaine is altogether the best dilator of the pupil when dilatation of the pupil alone is sought; it is especially applicable to the eyes of elderly persons in whom such an action is most frequently needed; and its known power of lowering the tension of the normal eye, and the ease with which eserine overcomes its action, make it apparently least liable to cause serious outbreaks of glaucoma.

Under the head of the *influence of cocaine on the cornea*, I would call attention to certain phenomena, the more striking of which are presented by the cornea; and which should never be forgotten when cocaine is applied to the eye. Cocaine powerfully influences corneal nutrition, perhaps by its effect on nutrient vessels, perhaps in other ways, but certainly it does so. Many observers report that after the very free use of the drug the cornea sometimes becomes inelastic, flabby, and warped, making it difficult to bring properly together the edges of a corneal wound. Such a corneal change is incipient in a large proportion of the cases in which cocaine is used, and will reveal itself if properly looked for. I have never noticed it after the use of a two per cent. solution of cocaine, but I have not used such a solution nearly so much as the four per cent. I have detected it a few times after a single instillation of the four per cent. solution; and after repeated instillations it is quite common. The most delicate test of its presence is given in the irregular astigmatism it causes. This may be recognized subjectively by a blurring of test-type, or other small objects, and objectively by a delicate mottling of the pupil as seen in retinoscopy. When more pronounced the changes in the corneal tissue cause such irregularities in the corneal surface as are apparent by careful inspection of reflections therefrom.

This irregularity of surface is independent of any loss of epithelium. I have seen it come on while the eye was steadily under observation and the epithelium remained intact. I have produced it in my own eye by keeping the cornea exposed to the air after the instillation of two drops of the four per cent. solution. I have no doubt this simple irregularity of surface has given rise to some of the accounts of cases of sudden loss of the corneal epithelium. For in most of these, not all, it is not stated that the epithelium was seen to separate from the cornea, but that the cornea was suddenly found devoid of it, and when the relation goes on that the epithelium was found entirely regenerated in a few hours, or a day or two, without any considerable inflammatory reaction; I feel sure the case is one of this kind. For in my experience abrasion of the cornea under cocaine is followed rather by unusually severe inflammatory reaction—a fact to be borne in mind when removing a foreign body from the cornea by promiscuous scraping. The corneal change may proceed so far as to cause a notable haziness in that membrane. This is certainly favored by exposure to the atmosphere. And Würdinger,[1] experimenting on rabbits, caused very considerable corneal opacity by repeated instillations of a five per cent. solution; the production of the opacity being hastened by keeping the cornea exposed.

[1] Klin. Monatsblat. für Augenheilkunde, April, 1886.

It has been suggested, that it is by lessening the lymph supply of the cornea, and the outflow of aqueous humor when the anterior chamber is opened, as well as by anæsthesia, allowing unnoticed contact of foreign matters, that cocaine makes the eye more susceptible to various injurious influences.

That cocaine is not the only factor in the causation of such corneal opacity is suggested by a correlation of the experience of Bunge[1] and Wood-White.[2] The former, in Gräfe's clinic at Halle, had long used a corrosive sublimate wash to cleanse the conjunctiva prior to operations, without bad effects. Cocaine was introduced, and a series of cases presenting a peculiar parenchymatous opacity of the cornea ensued. Wood-White had used cocaine some months, without having any such trouble. He then substituted corrosive sublimate for boric acid as his disinfectant, and soon had five similar cases to record. He ceased using the mercuric chloride, and no more cases occurred.

Very often the use of cocaine in a normal eye is followed after three or four hours by a little feeling of irritation and smarting, and this condition attends upon a slight but very perceptible hyperæmia of the conjunctiva. When cocaine is used in an eye affected with acute conjunctivitis, the suffering is for the time relieved, but after an hour or so returns with increased severity. Noticeable inflammatory symptoms after the removal of a foreign body from the cornea, have, with me been a little more frequent, I think, since I have used cocaine. In at least four cases of corneal and conjunctival inflammation I have felt quite sure that matters were worse from the injudicious use of cocaine. This is one of them.

Mrs. R., æt. thirty-three, was seen in consultation for inflammation of the left eye. The lids were moderately swollen, the palpebral conjunctiva thickened and velvety, the ocular conjunctiva moderately hyperæmic. But there was a narrow, very dark, purplish pericorneal zone, and from the lower margin, over half the surface of the cornea, stretched a perfectly superficial ulcer. The bottom of the ulcer was faintly gray, not infiltrated, and bore here and there patches of gray, sloughy membranous tissue, which, at the margins of the ulcer, were continuous with the surface of the sound cornea beyond. Great pain was complained of, and evidenced in face and actions, comparable to that from corneal abrasion in nursing women, but proportioned to the greater extent of the ulcer. The tension of the globe was below normal. The patient, who was subject to asthma, had, three weeks before, a light attack of pleuro-pneumonia; and then some conjunctivitis, which, for a few days, had not been serious, and then, under treatment, had grown rapidly worse until I saw her. A 4 per cent. solution of cocaine had been prescribed, to be used every four hours. The application of it gave temporary relief, but, as the pain soon returned, she had the application repeated without the knowledge of the attending physician, sometimes as often as every hour. I stopped the cocaine, tapped the anterior chamber, bathed the eye with hot water, and put her on the use of atropia and hot stupes. The severe pain was at once relieved and did not return. Two days later the ulcer was free from sloughs and had a uniform gray base. From that time the eye steadily improved; but, after two months, though free from hyperæmia, presented a cornea nebulous, and slightly irregular over the whole area of the ulcer, and vision, with the best correcting lens, was but $\frac{15}{50}$.

In using cocaine in the eye, one should apply no more than is necessary; take especial care to guard the cornea from other injurious influences; and never place the drug in the hands of the patient for the relief of continuous, or frequently recurrent pain.

MEDICAL PROGRESS.

HOW IS HEAT STROKE FATAL?—BONNAL, in a communication to the French Academy of Sciences, on July 4th, reached the following conclusions: His experiments were 130 in number, extending over six years; they were made upon men, in a hot liquid; in a dry oven; and in a moist oven; with the body naked and covered.

Life is possible at a higher temperature than that of the body. Tolerance of heat is greater in dry than moist air.

Loss of weight is proportionate to height and duration of temperature.

Lost weight is regained in twenty-four hours; if great, urinary secretion is suspended, to reappear when the loss is made up.

Physiological effects of heat are proportionate to height and duration of temperature; they are enhanced by moisture. The order in which they show themselves is variable, generally pulse and respiration are incoördinate; these deviations from physiological conditions precede more serious sequences.

Evaporation plays a very small part in the tolerance of heat; perspiration is generally most abundant in the most serious conditions. Death results from paralysis of the sympathetic nervous system, and failure of vital coördination.

Elevation of bodily temperature is an effect, not a cause, or a symptom.

Cold affusions are useful only by their effect on the nervous system.—*Gazette Hebdomadaire*, July 15, 1887.

KÉFIR, A NEW KOUMISS.—The following account of this beverage is taken from *Le Pratique Medicale*, No. 10:

It can be made from the milk of different animals, but it is generally made from cow's milk. Fermentation is excited by the presence of the kéfir, which is a species of mushroom, white when fresh, and yellow when old and dry, compact, elastic, and about one-fiftieth of an inch in diameter.

Chemically it is composed of water, fat, peptone, and nitrogenous material.

Examined microscopically it is composed of the rods and cells of beer-yeast.

It is found in the mountains of northern Caucasus near the snows. The natives believe that it is produced

by the bushes which grow upon the mountain-tops. It is probable that the first origin is in the great number of bacteria which circulate in the atmosphere, and whose soil of development is furnished by the curds of coagulated milk.

At the beginning of the preparation of kéfir the grains should be allowed to swell in tepid water for five or six hours—two teaspoonfuls to a tablespoonful of kéfir grains; they should then be washed in cold water and put in half a glass of fresh milk, which is changed every three hours. The grains, which were yellow, become white, and are then ready for the preparation of kéfir.

This is done by placing the white grains in a quart of fresh cow's milk, and the whole placed in uncorked bottles and exposed to a temperature of about 45° F., and frequently shaken. The milk begins to ferment soon, and in seven or eight hours the mass is fermented. The kéfir grains are removed by filtering through muslin, the liquid replaced in bottles, which are only partly filled, and carefully corked.

The milk is left at a constant temperature, and shaken every two or three hours. Fermentation continues in spite of the absence of the ferment, and in twenty-four hours the drink is ready. The grains of kéfir may be washed and used indefinitely.

Kéfir is richer in albumen than koumiss, less alcoholic, and less acid.

The following table of analysis shows the composition of milk, koumiss, and kéfir:

	Cow's milk.	Koumiss.	Kéfir.
Albumen . . .	48	11.2	38
Butter . . .	38	20.5	20
Sugar of milk . .	41	22.0	20
Lactic acid . . .	...	11.5	9
Alcohol . . .	...	16.5	8
Water and salts . .	873	918.3	905

Apon, a Compound Tincture of Thymol.—Poulet has suggested the following, as a convenient way of administering thymol:

R.—Tinct. capsici . . .	20 parts.
Ammonii liquid . . .	10 parts.
Essent. thymi,	
Chloral hydrat. . . .	ää 1 part.
Alcohol (60 per cent.) . .	100 parts.

To be kept tightly corked.

Sig.—10 to 20 drops in water; a half glass of water to be taken half an hour afterward.

This preparation may be mixed with oils and used as a liniment.

It is used as an analgesic.—*Deutsche medicinische Wochenschrift*, July 14, 1887.

Tubo-ovarian Cystic Pregnancy; Abortion; Death.—A case of unusual medico-legal and pathological interest is described in the current number of the *Archiv für Gynäkologie*, by Dr. Paltauf, of Vienna. A woman, aged twenty-eight, previously regular, missed a period at the end of June, 1886. Directly believing that the amenorrhœa was due to impregnation, she induced a midwife to procure abortion. On July 1st, several injections, of what fluid is not stated, were thrown up into the uterine cavity, by the aid of a gum-elastic catheter. These injections caused abdominal pain, and the first was followed by slight hemorrhage. During the next fortnight the patient suffered from constant pain and feverishness, and had for the greater part of that period to keep her bed. She was treated by her medical attendants for parametritis and pelvic peritonitis. A resistant body could be detected in the posterior vaginal fornix on digital exploration; it was not very tender. At length the patient became prostrated, diarrhœa set in, and she died on July 26th, after having admitted the cause of her illness. Dr. Paltauf was ordered, by the legal authorities, to make a necropsy. He found evidences of universal peritonitis, and the pelvic viscera were firmly matted together. The vagina was capacious, its rugæ effaced, and its mucous membrane of a grayish-violet color. The uterus was enlarged; behind it was an oval cyst over three inches in its long diameter. The relations of this cyst, which contained an embryo seven-tenths of an inch long, were most remarkable, and are fully described in Dr. Paltauf's paper. There was a tubo-ovarian cyst on both sides, and the large embryo-bearing cyst behind the uterus was part of the left tubo-ovarian cyst. A most unique feature was the free communication which was discovered to exist between the uterus, the tubes, and the cysts, so that there was a free passage from either side of the cavity which contained the fœtus into the uterus and *vice versâ*, without any opening into the peritoneum. The parenchyma of each ovary was uncovered, flattened out, on the surface of each cyst, but distinctly connected with the uterus by the ovarian ligament. Hence gestation had occurred in a case of probably congenital double tubo-ovarian cyst with ovaries malformed, yet perfectly able to carry on their functions. The necropsy and the evidence brought forward at the judicial inquiry proved that deceased had died of septic peritonitis, that she was in the second month of a tubo-ovarian cystic pregnancy; that the embryo was alive at or shortly before the death of the mother, and had no share in causing her death; that the infection was introduced from without into deceased's body; that the mechanical attempts to procure abortion were most probably the source of infection; that the nature of the peritonitis corresponded with the duration of the morbid processes; that the abnormal pregnancy could not have terminated in the ordinary manner, nor by the usual means whereby abortion is procured, and was not necessarily the cause of the mother's death; and that the action of the midwife might have terminated a normal pregnancy. The midwife was found guilty not of criminal abortion, but, according to Austrian law, of an offence against the safety of human life.—*British Medical Journal*, July 16, 1887.

Casein as an Emulsifier, is proposed by M. Léger in *L'Union Pharm.* of May 15th, on account of its permanence, and the ease with which it may be handled. To separate it, he treats 4 quarts of milk with 15 drachms of ammonia for twenty-four hours, and, after removing the saponaceous matter from the surface of the mixture, precipitates the serum with acetic acid. The magma of casein, strongly pressed, is treated with sodium bicarbonate, with a sufficient quantity of sugar to make the dried product contain one-tenth of its weight of casein. The powdered substance dissolves easily in water, and,

mixed with its weight of gum, may be used for almost all of the emulsions. Resinous matters and balsams, previously dissolved in alcohol, essences, and oils, may be mixed with it in the bottle itself, without using the mortar. The only defect in this saccharate of casein is its slight animal odor, which, it is believed, can be counteracted.—*American Journal of Pharmacy*, July, 1887.

LANIUM ALBUM (NETTLE) IN THE TREATMENT OF UTERINE HEMORRHAGE.—FLORAIN reports good results in metrorrhagia, where other drugs had failed, from the use of the following:

Tinct. lamii albi	. . . .	10 parts.
Syrup simpl.	. . . .	5 parts.
Aquæ	. . . . .	2½ parts.

A teaspoonful may be taken every half hour until hemorrhage is checked, and then every four hours. The drug is easily taken and well borne.

It contains tannic and gallic acids and nitrates, upon which its astringent properties depend.

An alkaloid, *sulphate of lamine*, has been isolated, which is sparingly soluble in water, but soluble in hydrochloric and nitric acids. Its exact analysis has not been made.—*Gazette de Gynécologie*, July, 1887.

MEMBRANOUS ENTERITIS; INTESTINAL PERFORATION; PERITONITIS; DEATH.—At a recent meeting of the Society for Internal Medicine at Berlin, Rothmann reported the case of a patient who had repeated discharges of blood and fibrinous masses with symptoms pointing to a localized ulceration; perforation, peritonitis, and death followed. Post-mortem revealed a knuckle of intestine adherent near the junction of the stomach and duodenum. The adhesions had ruptured, and the finger found an annular constriction in the intestine.—*Deutsche medicinische Wochenschrift*, July 7, 1887.

CASTRATION FOR TUBERCULOSIS OF THE TESTICLE.—FINCKH publishes some statistics on a basis of twenty-nine cases of castration performed for tuberculosis of the testicle in the surgical clinic at Tübingen. In some cases the time of observation after the operation extended to thirty years, and at the least to one year.

He warns against the partial extirpation of the testicle, which has been recommended by some, to preserve for the patient the "illusion" of virility, rightly claiming that it is impossible to be certain that the rest of the testicle is really healthy, and with respect to the psychic effect of castration, he quotes the case reported by Simmonds, in which double castration for tuberculosis relieved the patient of decided hysterical symptoms.

The epididymis is the most frequent starting-point for the tubercular process, much less frequently the body of the testicle, and only now and then the seminal vesicles, or the prostate. The infection very rarely descends from the kidney to the genital organs. The tuberculosis frequently spreads from the epididymis to the body of the testicle, and sometimes to the tunica and the scrotal tissues. The tunica is often the seat of miliary tubercles. The infection may extend along the vas deferens to the prostate and seminal vesicles, and it may reach the testicle of the other side, by descending its vas deferens. But out of eight cases in which double castration was performed, Finckh found the vas deferens healthy on both sides at the time of operation in five, and in two it was diseased on only one side. In the remaining cases both cords were tuberculous, and on one side the changes extended within the pelvis, so that some diseased tissue was left after extirpation, and yet the patient lived twenty-three years after. In like manner, Simmonds found the prostate healthy in three cases out of five of tuberculosis of the epididymis of both testicles, consequently the disease must have had an independent origin upon both sides, or the infection was able to pass through the prostate without affecting it. The existence of disease in both testicles, then, does not prove that the intrapelvic parts are involved, and even if they are, recovery is possible, although the whole disease tissue cannot be removed—therefore the opinion held by some, that castration is contraindicated when the tuberculosis exists upon both sides, is erroneous.

It has generally been supposed that if the intrapelvic parts of the genital organs were tuberculous, the prognosis was hopeless, and yet in seven cases in which some diseased tissues had to be left in the cord, none had recurrence—the elapsed time of observation after operation being 24, 6, 5, 3, 2, and 1 (2 cases) years. Finckh does not seem to be familiar with the fact that in the two cases of spontaneous recovery from tuberculosis of the testicle, proven by autopsy, quoted by Reclus, the prostate was involved when the process was at its height. Unfortunately Finckh does not give any facts as to the prognosis when castration is not performed.

The youngest of Finckh's cases was 8 years old, the next 18, the oldest 63. Of the 29 cases 6 died subsequently of tuberculosis of various organs, but no local recurrence was noted. One of these cases died of miliary tuberculosis three weeks after the operation. The longest duration of life of these six cases was four years, and adopting this period as the extreme limit during which recurrence is to be expected, there are 13 cases which can be set against them, in which no recurrence took place within that time.

The duration of the disease at the time of operation is not considered, but from the accompanying histories of the cases we learn that in the six cases which died of tuberculosis, the duration of the disease before operation was 1 month, 6 months, 18 months, 2 years (2 cases), and of one case not given. Of the other cases there are seven in which the duration was over one year (in two cases, three years), all remaining free from tuberculosis five years after the operation. Therefore long duration does not necessarily contraindicate castration. Only one case died from the operation, an old man, of "exhaustion."—*Annals of Surgery*, July, 1887.

FORMULÆ FOR AMYLEN-HYDRATE, A NEW HYPNOTIC.—VON MERING advises the following:

R.—Amylen-hydrat.	. . . .	℥5.
Aq. dest.	. . . .	3ij5.
Extr. liquir.	. . . .	3ij½.

Half of this may be taken on retiring.

Also,

R.—Amylen-hydrat.	ℳ75.
Aq. dest.	312½.
Mucilag. gum arab.	35.

To be used per rectum. The drug may be combined with morphia as follows:

R.—Amylen-hydrat.	ℳ90
Morph. hydrochlor.	gr. $\frac{8}{10}$.
Aq. dest.	315.
Extr. liquirit.	32½.

Half of this may be taken on retiring.

Also,

R.—Amylen-hydrat.	31.
Morph. hydrochlor.	gr. $\frac{1}{2}$.
Aq. dest.	312½.
Mucilag. gummi arab.	35.

Which may be given per rectum.—*Therapeutische Monatshefte*, July, 1887.

The Motor Power of the Stomach and the Influence of the Electric Current.—Professor Ewald has enriched our diagnostic resources by a new procedure for investigating the motor power of the stomach (Berlin Medical Association, June 15th). We know pretty well the chemical changes taking place during digestion, but our experiments on the time required by the stomach for transmitting food into the duodenum have hitherto been limited to patients suffering from gastric fistula. Trials made in the normal state of health have always failed. A means has now been found in salol excellently adapted to solve this question. Nencki, who discovered salol, has stated that it remains undissolved in the stomach, but is decomposed into phenol and salicylic acid by the pancreatic juice. The first part of this dictum is correct, the latter incorrect; for salol is decomposed by any neutral mucous membrane, whilst the juice of the pancreas seems rather to delay the decomposition. Salol, on reaching the bowels, immediately dissolves, and shows almost instantly in the urine as salicyluric acid. This easily yields a red precipitate with chloride of iron. This reaction will show almost exactly the moment of the entrance of food into the bowel. The urine of seven persons in sound health showed the reaction to take place mostly within three-quarters of an hour, rarely within half an hour. It took two to three hours in seven cases of "ektasia ventriculi," this disease being distinguished by loss of motor power in this organ. On applying the electric current to the abdomen, the reaction took place in normal cases a quarter of an hour sooner; in cases of enlargement of the stomach, half an hour sooner. This experiment says much in favor of this method of treatment, which is despised by so many physicians. Science owes to Professor Ewald a discovery equally important in theory and in practice.—*British Medical Journal*, July 2, 1887.

A Routine for Oestetric Practice.—Dr. Duncan, of the Middlesex Hospital, advises the following for all obstetric cases:

Assuming, then, that the sanitary arrangements, both of the lying-in chamber and of the house in which it is situated, are perfectly sound, I venture to suggest that every obstetric case should be conducted somewhat as follows: The medical attendant, before visiting his patient, ought to feel confident that he does not carry in his clothes the means of infection. Before making a vaginal examination the hands should be thoroughly washed with carbolic soap and water, using always a nailbrush, and then the forefinger smeared with some antiseptic. (I always use a 1 in 500 solution of corrosive sublimate in glycerine.) The vagina is to be washed out before the birth of the child with a warm solution of either 1 in 40 carbolic acid, or 1 in 2000 sublimate. For the five days following delivery the vagina is to be washed out night and morning with a 1 in 2000 sublimate solution, and from then until the lochia have ceased with a solution of half the strength. Any perineal laceration should be sutured, and in any case where it has been necessary either to apply the long forceps or to insert the hand into the uterine cavity, this latter should be washed out by means of a double pipe, and then a thirty grain iodoform bougie passed well into the uterus. The nurse should take precisely the same precautions as the practitioner with regard to her hands before attending to her patient. She should be careful to remove all soiled linen from the room, and to keep the catheter and the vaginal pipe immersed in a basinful of 1 in 40 carbolic or 1 in 2000 sublimate solution. If every woman's lying-in were to be conducted on the lines above indicated, it seems to me we should very rarely meet with that fearful malady, puerperal fever.—*Lancet* July 16, 1887.

Cocaine in Mental Diseases.—Heimann, of Charlottenburg, Berlin, writes as follows of his experience with cocaine in mental disorders in the *Journal of Mental Science* for July, 1887:

Certain therapeutic effects upon the human organism ascribed to cocaine, occasioned me to make use of the drug in suitable cases of psychosis and psycho-neurosis. Stimulant action and exhilaration (Euphoria) on the one hand, and on the other depression of undue sensitiveness, these were the effects I looked for from the alkaloid. Unfortunately, I am able to record scarcely a single case of certain and permanent cure following the use of the drug.

In melancholia, without hallucinations, cocaine was ordered in doses of 0.01 gramme thrice daily; the dose was increased up to 0.06 gramme (in English weights grain $\frac{1}{6}$ to grain $\frac{2}{3}$). At the end of a fortnight the treatment was obliged to be abandoned on account of failure to health, due to anorexia; the drug had been quite without effect on the psychosis. No secondary effects were witnessed with the exception of acceleration of pulse and dilatation of pupil, both of which lasted some three or four minutes. The small doses were chosen in order to avoid the production of hallucinations.

In melancholia with hallucinations cocaine was given in doses of 0.02 gramme ($\frac{1}{3}$ of a grain) about thrice daily, again without success. One of these latter patients suffering from hypochondriacal delusions, stated that for a very short time after taking the drug (one to two minutes) he felt easier. After fourteen days, when no advance had been made, but on the contrary, complete anorexia had supervened, the drug was stopped.

To test the vaunted influence of cocaine on the motor centres, the drug was administered subcutaneously in doses of 0.02 gramme ($\frac{1}{3}$ of a grain) per diem, to two patients suffering from katatonia; the drug was continued for several weeks without the slightest effect.

Finally, even in cases of hypochondriasis, neurasthenia, and hysteria in which I looked for great success, having regard to the exhilarant effects described, even here there was complete absence of any obvious or permanent improvement. The hypochondriacal patient, who hails with gladness every new remedy, was soon obliged to complain, and with justice, of anorexia. The subject of neurasthenia complained more and more of weakness, being unable to take sufficient nutriment. In hysterical patients besides anorexia, which, by-the-bye, is not to be disregarded, owing to the frequent coexistence of anæmia, there occurred attacks of vertigo, which soon lessened their faith in the medicine. From these, my observations, I am constrained to deny to cocaine a place in the therapy of mental disease.

OUTLINING THE STOMACH BY PERCUSSION.—The following method, for which novelty and utility are claimed, is advocated by RUAULT in the *Gazette Hebdomadaire* of July 1, 1887:

The patient is to be placed on his back, the arms raised, the hands behind his head. The physician, facing the foot of the bed at the patient's left side, places his ear upon the left false ribs. With his left hand he percusses from the left border of the sternum in a straight line toward the abdomen. He so continues, from left to right, until he has outlined and marked on the skin, if desired, the peculiar resonance of the stomach. In doubtful cases fluid or gas may be introduced into the stomach with advantage.

DIABETES AND GLYCERINE.—W. B. RANSOM, of Trinity College, Cambridge, reports the following conclusions from experiments bearing upon this subject in the *Journal of Physiology*, vol. 8, No. 2.

These experiments tend to show:

1. That certain forms of glycosuria may be checked by glycerine.

2. That glycerine acts more efficiently when introduced into the alimentary canal than when injected subcutaneously.

3. That glycerine checks glycosuria by inhibiting the formation of sugar in the liver.

3. That in this way glycerine may lead indirectly to an accumulation of glycogen in the liver.

Viewing the formation both of glycogen and sugar as a process of cell metabolism, quite independent of ferment action, he is unable to suppose that glycerine produces its effect by acting on a ferment in the blood, but considers it probable that it excercises some direct influence on the protoplasm of the liver cells.

Of a possible therapeutic use of glycerine in diabetes mellitus he is not now in a position to speak. The reports of clinical observers are very various, and his own observations are as yet too few to form a basis for definite conclusions.

SUPRAPUBIC CYSTOTOMY FOR A FOREIGN BODY AND CALCULUS.—DR. GILLON, of Wellington Hospital, New Zealand, reports in the *British Medical Journal* of July 30, 1887, the case of a man, who in 1884, in endeavoring to dislodge a calculus with a pen-holder pushed the latter into the bladder. The operator found a calculus encrusted upon the holder, both weighing 2¾ ounces. The patient made an uninterrupted recovery.

THE TREATMENT OF LARYNGEAL PHTHISIS IN THE STAGE OF ULCERATION.—ASTIER gathers the following methods of treatment:

1. For pain,

Ext. opii,	
Ext. belladonn.	ää gr. 8.
Dissolve in aqua lauro-cerasi. .	℥ 5.

Used locally.

Insufflations of $\frac{1}{10}$ of a grain of morphia mixed with starch, as advised by Mackenzie, may be used twice daily; and the dose may be increased to ½ a grain.

Moure employs 5 grains of hydrochlorate of morphine in 15½ ounces of water by spray.

Astier employs the following powder by insufflation:

Plumbi acetat.	gr. 30.
Morph. hydrochlorat.	gr. 3.
Sacchar. lact.	℥ 2½.

To be applied after cleansing the mucous membrane by solutions of potassium chlorate or sodium bicarbonate.

2. The ulcerated surfaces may be cauterized by nitrate of silver, galvano-cautery, tincture of iodine, or

Iodin.	gr. 5.
Potass. iod.	gr. 45.
Glycerin.	℥ 2½.

Iodoform, in suspension in glycerine, or in powder may be used.

3. If œdema be present, tracheotomy may be necessary.

4. Forced feeding, and preliminary anæsthesia by cocaine, before introducing a stomach-tube, may be needed.

The lactic acid treatment (Krause) consists of the use of solutions of from 10 to 80 per cent. of the acid; from which good results have been obtained.—*Journal de Medecine*, July 24, 1887.

WHAT IS THE SEMILUNAR SPACE OF TRAUBE?—It will be remembered that TRAUBE was the first to draw attention to this region of the body in his studies of the physical signs of pleurisy; the space which bears his name is of interest to diagnosticians in examining the stomach; it is given thus by *Le Progrès Médicale* for July 23, 1887: "It is that portion of the left inferior anterior thoracic region corresponding to the tympanitic resonance of the stomach." Its determination is effected by following the usual rules for percussion.

TUBERCULOSIS IN CATTLE.—MÜLLER concludes, from an extensive series of experiments, as follows: Forms of tuberculosis similar to those in the human subject are readily produced in cattle, as diffuse osteomyelitis, miliary tuberculosis of bones, which in the greater number of cases develop freely in six weeks after infection with well-marked symptoms.—*Centralblatt für die medicinischen Wissenschaften*, July 16, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance. . . . . $5.00.

Single Copies. . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, AUGUST 27, 1887.

THE MEDICO-LEGAL SIGNIFICANCE OF TWO OR MORE MORTAL WOUNDS.

Interesting and instructive papers have lately appeared in The Medical News, by Surgeon Alfred A. Woodhull and Prof. D. Hayes Agnew, upon this subject. Since then the lamented death of Lieutenant Arthur H. Clarke, U. S. N., who is believed to have destroyed himself by a pistol-shot on board the "Iriquois," a few months ago, brings again before us the oft-mooted question, whether it is possible for a person to inflict upon himself, consecutively, two mortal wounds, say by shooting, one bullet through the brain and another immediately afterward through the heart?

The medico-legal interests connected with this question will be immediately apparent when we consider the issue involved. If, for example, we deny the possibility of a suicide, after having inflicted upon himself a wound which we judge must have been immediately fatal—such as that caused by a pistol-ball or a dagger through the heart, or by a bullet tearing through the brain—repeating the latter act by a *second* equally fatal wound, then in a case where a dead body is discovered displaying two such mortal wounds, our only inference could be that it was a case of homicide and not a suicide. On the other hand, if we admit the possibility of a person fully determined on self-destruction, having failed in his first effort to destroy himself *instantly*, to repeat the deadly act, so as not to be foiled in his attempt, then the case assumes a very different aspect. An innocent person, arrested, possibly under suspicious circumstances, might be tried for murder, and even convicted under the former view of the case, whilst under the latter view the suspected person might be very justly acquitted of all complicity in the case, and the death be chargeable solely to the unhappy suicide himself.

The importance to the medical jurist of clear views on this subject cannot be over-estimated. The case referred to by Surgeon Woodhull was that of a man found in bed, unconscious, with a pistol-ball that had gone crashing through his brain, and contusing the opposite parietal bone. He still held the fatal weapon tightly grasped in his hand. Two chambers of the revolver had been discharged. The second ball had passed up through the ceiling, obliquely, some little distance from the side of the body. In this case there could be no doubt whatever that the act was suicidal. There was no second wound on the body. The only point of interest in connection with our present subject is the fact of the *second* discharge of the weapon. Was it intentional on the part of the suicide, or was it a mere automatic act? Was the man capable, after having shot himself through the brain (the wound being not immediately fatal), of again voluntarily firing his pistol? Or did he, as Surgeon Woodhull inclines to believe, unconsciously, with his finger yet on the trigger of a self-cocking pistol, exert an automatic pressure on that trigger, as his arm would necessarily relax and partially fall, so as to discharge the weapon, as before mentioned? There seems to be sufficient grounds for adopting the latter view in this particular instance, inasmuch as even assuming the man's ability consciously to fire a second shot, it would certainly have taken a different course, namely, through his own body. The only other possible alternative to adopt is the idea that the shot through the ceiling might have been the first one fired—"a trial shot, to determine whether the weapon was in good working order."

We think that the above case certainly warrants the presumption that, under similar circumstances, where a self-cocking pistol has been *twice* fired, the second shot may very possibly have resulted from an automatic, unconscious act—on the part of the suicide. Nor need this theory be necessarily negatived, even if the second (supposed) shot has entered a vital part of the body, instead of striking some outside object, since it is quite conceivable that such a chance-shot might equally be directed toward the man's body, depending entirely on the particular position assumed by the relaxing arm.

The medico-legal point in such a case is just that suggested by Dr. Woodhull. "Another person might have been fatally wounded by this second shot. In that event, the discovery of two bodies might have led to the suspicion of murder followed by suicide; while, in fact, there would have been suicide followed by involuntary manslaughter."

Prof. Agnew's interesting article opens with the

question whether " it is possible for an individual, with suicidal intent, and in quick succession, to inflict a perforating shot wound in the head and another in the heart." In a case in which he was called as an expert, he held that it was, and we think his view is capable of abundant proof. But, first it is necessary to disabuse ourselves of the notion that wounds of the brain and heart are always immediately fatal. Indeed, as regards the former, we have abundant evidence that they are by no means always mortal; numerous cases are recorded of recovery after the most frightful wounds of the head, involving even a loss of a considerable portion of the brain. After a severe wound of this organ, the only conditions disqualifying the individual from voluntarily repeating the attempt upon his life would be either immediate loss of consciousness, or immediate paralysis of the voluntary muscles. The records of surgery show that neither loss of consciousness nor paralysis necessarily follows gunshot wounds of the brain; the occurrence of the paralysis being altogether dependent upon the particular areas or portions of the cerebral mass involved, so that this factor must be eliminated in the discussion of this question. Given then, the *ability* of the individual thus circumstanced, together with an unimpaired *will*, we can see no impediment to his repeating the attempt at self-destruction.

Secondly, as regards wounds of the heart, the records fully demonstrate the fact that such injuries are by no means immediately fatal; indeed, in not a few instances recoveries have taken place. The periods of survival in fatal cases have varied from a few hours up to several months. Hence there is no difficulty in admitting the possibility of a determined suicide making a second, or even a third attempt upon his life, in case the first one—even though it be a mortal wound of the head or heart—was not immediately fatal.

To place this matter beyond all question, the testimony of Prof. MacLeod, of the University of Glasgow, quoted by Prof. Agnew, and the records of the office of the Coroner of this city also show a number of similar instances of multiple wounds suicidally inflicted. One is that of a policeman who first shot himself through the head, and immediately afterward through the heart. This was done in the presence of witnesses. Another case is that of a lad aged nineteen years, who inflicted four shot wounds from a revolver on his own person. The first bullet entered the forehead, and after taking a circuitous route, lodged about the middle of the left temporal lobe. A second ball was fired into the chest, passing through the left ventricle of the heart. A third shot passed through the abdomen; and the fourth into the neck. Death ensued from pericardial hemorrhage. A third case is that of a grocer who was found dead in his room, having locked the door. A pistol was still clutched in each hand; one bullet had passed through the brain, and a second through his heart.

From the foregoing statements we think the following propositions are sustained:

First. The presence of two or more wounds in a dead body is not inconsistent with the idea of suicide. There is abundant proof to show that a person determined on self-destruction, may first shoot himself in the head, and immediately follow it up by a shot through the heart, or *vice versâ*.

Secondly. In the case of two bullet-wounds in a suicide, made by a self-cocking pistol, it is quite possible that the second wound may have been inflicted unconsciously and automatically in the descent of the arm after firing the first shot. This, however, could only occur where a self-cocking pistol had been the weapon used; we do not believe it to be possible with an ordinary pistol.

Thirdly. In an unknown case, and in the absence of all evidence, the presence of several wounds upon a dead body would generally be suggestive of murder; although, as we have seen, it might not be positive proof of it. The nature of the wounds, their position and direction, are the important circumstances which would here have to be considered.

AMYL HYDRATE—A NEW HYPNOTIC.

In the *Therapeutische Monatshefte* for July, 1887, PROFESSOR MERING, of Strassburg, calls attention to a substance known as amyl hydrate, which possesses hypnotic powers, and belongs to the group of tertiary alcohols. When a small dose was given to a frog, it produced a failure of reflex action, and finally sleep. In the higher animals, such as the dog or rabbit, deep sleep was the first symptom to assert itself, the loss of reflex action following it. The advantages which Mering claims for amyl hydrate is that it has but little effect on the circulation as compared to chloral, its chief influence being upon the respiratory system, so that in those animals to whom a lethal dose was administered death came by failure of respiration. In large doses, however, it very greatly depresses the heart, and it can scarcely be said to be a drug which can be used fearlessly.

The clinical side of Professor Mering's paper records the use of amyl hydrate in a very large number of cases in which we are generally accustomed to use chloral. He has found it useful in delirium tremens, and all morbid conditions of nervous matter, and has also used it with good results in the insomnia of phthisis. Generally he administers it in the form of a clyster, in a mixture consisting of seven parts of amyl hydrate, fifty parts of water, and twenty parts of mucilage of acacia. When pain is associated

with the insomnia, he adds a small dose of the muriate of morphia.

GASEOUS ENEMATA IN THE TREATMENT OF PHTHISIS IN GERMANY.

German physicians have shown their customary reserve in the adoption of expedients whose utility is not based upon the soundest of pathological grounds in adopting the recently examined treatment of phthisis by enemata of gases. At a recent meeting of the Society for Internal Medicine, of Berlin, Statz reported the results which he had obtained in treating ten patients in Fräntzel's clinic, eight of whom were advanced in the disease. The treatment was thoroughly tried for periods varying from nine days to sixteen weeks. In six cases the physical signs were improved. In all general palliation ensued, but in none were the bacilli influenced. The improvements in appetite and weight were lost as soon as treatment was suspended. The value of the treatment seemed to be entirely palliative and transient. Further trial was urged by Statz, but in the ensuing discussion Ewald stated that he could not see grounds for placing reliance upon the method.

THE PROGNOSIS IN THE CASE OF THE CROWN PRINCE.

The résumé of Virchow's paper on Pachydermia Laryngis, which we print to-day, and the published reports of his examination of the fragments of the growth removed by Dr. Mackenzie from the larynx of the Crown Prince of Prussia, leave no doubt as to the opinion of this great pathologist as to the benign character of the morbid growth. No epithelial elements were found in those portions of submucous connective tissue which were removed in the second operation. Their presence, according to the tenor of his paper, would have declared the affection to be cancerous, no matter what the character of the surface tissue. Deep connective tissue was not furnished in the specimen last examined, and proliferation of epithelial masses was found in the superficial portion only, but in no position did this proliferation attain the character of independent formation. He states that this excised piece, in still greater degree than that previously removed, presented the appearance of a hard compressed wart, the base of which did not contain the remotest evidence of a neoplastic penetration into the tissue.

Virchow, in plain language, has not discovered any appearances indicative of malignancy in the specimens examined, and from his knowledge of pathology he does not hesitate to pronounce the morbid growth in the Crown Prince's larynx to be a simple wart without any cancerous tendency. The fact of recurrence does not militate against this view, and he expresses the opinion that every recurrence of the growth can be successfully removed as it presents, until, as in the history of similar cases, final eradication is accomplished.

With profound regret we record the death of Nathaniel Archer Randolph, M.D., which occurred on Sunday last, while bathing in the surf at Longport, N. J., whither he had gone to secure a day's needed rest.

Dr. Randolph was born in the neighborhood of Philadelphia about thirty years ago. He received a liberal education at Cornell University and graduated in medicine at the University of Pennsylvania in 1882. He subsequently pursued in Germany his studies in physiology, therapeutics, and the relation of foods to nutrition in which subjects he was specially interested. Last year his qualifications as a lecturer received early recognition by his election to succeed the late Dr. J. G. Richardson, as Professor of Hygiene in the University of Pennsylvania.

Dr. Randolph possessed cultivated tastes, a benevolent disposition, and a high sense of professional responsibility; he was a capable teacher, an accomplished student, and an able writer. His last published research was a thoughtful, physiological study on the irradiation of motor impulses, which was read before the College of Physicians in March last. He was an active worker on the staff of The News until last May, when, with Dr. Dulles he assumed the management of *The Medical and Surgical Reporter*, and in this new field he labored with characteristic zeal. He has been cut off at the outset of a career which was full of promise of honor to himself and usefulness to his fellows, and a wide circle of sorrowing friends mourns his loss.

Dr. Pedro Francisco da Costa Alvarenga, of Lisbon, who died several years ago, childless and possessed of a large fortune, has willed the greater portion of his wealth to scientific and charitable institutions. Among his bequests he has left about $18,000 to the College of Physicians of Philadelphia, of which he was an Associate Fellow, and the same amount to the Medical Society of Berlin, at whose meetings he is said to have been a frequent visitor.

The American Gynecological Society will hold its annual session in the Hall of the New York Academy of Medicine on September 13th, 14th and 15th. Several distinguished British and Continental obstetricans and gynecologists have accepted invitations to participate in the proceedings.

The American Academy of Medicine will hold its eleventh annual meeting at Columbian College,

Washington, D. C., Saturday, September 3d, at noon. The annual collation will take place at the Arlington Hotel at 9 o'clock of the same evening.

The eighteenth annual session of the Medical Society of Virginia will convene in Richmond, Va., on Tuesday, October 18, 1887, at 8 P.M. A general discussion on "The Choice of Anæsthetics" will be opened by Dr. Hunter McGuire.

Dr. Charles G. Stockton has been elected to fill the vacancy caused by the death of Dr. Rochester in the medical faculty of the University of Buffalo. A Department of Veterinary Medicine is to be added to the University.

SPECIAL ARTICLE.

PACHYDERMIA LARYNGIS.

Prof. Virchow, under this title, read before the Berlin Medical Society, at its meeting on July 27, 1887, a paper which gives his views of the pathology of the throat affection of the Crown Prince of Germany.

In opening his paper Professor Virchow remarked that it would ill become him to omit mention of the fact that his discourse was occasioned by the serious illness of the Crown Prince, which had so largely engaged public attention during the past few months. After alluding to his early studies of the anatomy of laryngeal growths, he described the boundaries of the pavement epithelium of the pharynx, as it extended upon the laryngeal structures; referring especially to the broad strip of pavement epithelium which passed over the region between the two arytenoid cartilages, and is thence continuous without interruption upon the vocal cords to their anterior extremities. He remarked that these sections of the larynx covered with pavement epithelium, when compared with portions of the digestive tract, showed a type approaching the cutaneous cells; that their characteristics were more or less cutaneous or dermoid. This was especially shown in the continuity of the flat epithelium of the skin, as it extended through the mouth into the respiratory and digestive tract.

The processes which form the objects of interest in this epithelial tissue partake largely of the character of chronic inflammation, in the course of which two morbid processes are especially noticeable, viz., *a*. localized swelling, generally limited to a single point; *b*. diffuse swelling. Both are excessive epithelial proliferation; in the first the cells do not change their type, but greatly increase as dermoid cells; in the second a diffuse proliferation of the superficial connective tissue, rather than of the epithelium, takes place. Both processes Virchow names pachydermia; the limited or localized form he terms "warty" pachydermia, or pachydermia verrucosa.

As a characteristic appearance on examination he finds at the posterior extremity of the vocal cord, where the processus vocalis of the arytenoid cartilage passes beneath the mucous membrane, at its emergence, a flat, oval swelling, which extends generally obliquely from behind and above downward and forward beneath the border of the vocal cord. These bodies are symmetrical, and are not the scars of former ulcers, but epithelial layers closely adherent to the subjacent cartilage, and probably undergoing an erosive-like process. In addition to this there is a diffuse process which extends over the entire surface of the vocal cords, and consists of a superficial layer of grayish, thick material, which is made up of epithelial cells. Microscopic examination reveals a papillary structure covered with epithelia. A further extension of the disease is found in the interarytenoid spaces; this occurs, however, infrequently. In this condition an important feature is the occurrence of masses of hardened fissured tissue called rhagades, resembling the hardened portions of cutaneous callus. By the movements of the parts these masses wound the surrounding tissues, producing the appearances of cancroid ulcers. He does not believe that an actual change into cancroidal tissue occurs.

The most salient point of warty growths upon ordinary examination, is found at the middle and anterior portion of the vocal cords, and in the anterior angle where the vocal cords meet.

The best described form of pachydermia is that in which the papillary element is least well marked, the growth consisting of epithelia only. Such growths are generally called papilloma, a name which Virchow considers an absurdity; he shows how it is equally applicable to various tumors, and wishes that it was rejected from the literature as meaningless.

The essential characteristic of papillary proliferation in the larynx he considers to be the proliferation and hardening of the epithelial elements. Epithelioma is a much more appropriate name for the growth, which should be subdivided into hyperplastic and heteroplastic.

The diagnosis is difficult, and it can only be determined by anatomical examination whether the growth is heteroplastic or cancerous, or only superficial epithelial proliferation. The latter consists of a growth of the epidermal epithelium, amidst which the papilla grows. Such symmetrical growths are often found in connection with nests of epithelial cells. According to Virchow, the verrucosities of the larynx are of epithelial nature, and were formerly called condylomata, but this name is now reserved for another form of tumor. Another gross error in the classification of these growths has been in calling them fibromata; when sections are properly made it will be found that in no instance does the connective tissue proliferate into the epithelium, but the growth is an epithelial proliferation. It is not difficult, by proper section, to study carefully the development of these tissues from nuclei, and from such observations the conclusion is reached that the disease pertains to the epithelium as such. Polyps may possess some of the characteristics of these growths, but not their combined peculiarities.

Virchow sums up his description as follows: In a certain portion of the larynx, caused by irritation

similar to that which exists on the external skin, two kinds of proliferation may occur which resemble chronic inflammation; one produces a warty growth, and one a diffuse, even swelling, which attacks the entire superficies. These resemble markedly the warts and diffuse swellings produced by irritation of various sorts upon the integument, causing a local increase of tissue. (In illustration of the differential diagnosis of these growths, specimens of lupus and papillary cancer were exhibited.)

Virchow's criterion of distinction between the papillary wart and the papillary cancer is the absence or presence of epithelial elements in the connective tissue. He considers all growths benign in which the normal demarcation remains at the base of the epithelial layer. Every trace of epithelium in the connective tissue he considers suspicious. When he finds beneath the boundary line of epithelium spaces filled with epithelial masses, then he recognizes the distinctive characteristic which stamps the formation as cancerous.

To determine the character of these growths, a thorough examination of the base of the tumor must, therefore, be made; when nothing foreign exists there, no matter what has developed on the surface, the growth is local and of a benign nature, nor will malignancy subsequently develop; but when beneath the boundary line spaces filled with epithelial cells are found, the growth is cancerous. It is evident that only comprehensive and properly made sections are available for diagnosis.

Recurrences of this papillary form of growth are frequent, and have been often observed. Repeated removals have succeeded in extirpating such masses. It is possible that such growths may spontaneously disappear, as do cutaneous warts. He has had no personal observations on this point, but others have observed such disappearance.

The full text of the paper will be found in the *Berliner klinische Wochenschrift* of August 8th.

REVIEWS.

Wear and Tear, or Hints for the Overworked. By S. Weir Mitchell, M.D., LL.D. Harv., Member of the National Academy of Sciences, President of the College of Physicians of Philadelphia, etc. Fifth edition, thoroughly revised. Philadelphia: J. B. Lippincott Company, 1887.

In the sixteen years which have elapsed since the first edition of this book was issued, the accumulation of property has removed a large number of Americans from the number of those to whom the author originally wrote. There will always remain, however, a large class engaged in mental labor with whom the struggle for existence often exceeds the limits of endurance. The problem of the conservation and direction of energy occupies not only the field of physics, but also that of neurology; and to those whose capital is nervous force, the book has proved a safe guide in avoiding the dangers of excessive labor. The book suggests several problems in American sociology, to whose solution his readers would gladly invite the erudition and facility of the author.

CORRESPONDENCE.

THE INTERNATIONAL MEDICAL CONGRESS.

In spite of the depressing influences o the heated term, busy preparations are going on by all concerned in the local management of the International Medical Congress. The office of the Secretary-General, Dr. Hamilton, shows tables filled with proof-sheets, titles and abstracts of papers, programmes, letters, etc., and medical men are constantly coming and going, seeking information on matters pertaining to the Congress. Dr. Hamilton showed me a closely printed pamphlet in small type, a proof copy, in which were embodied the titles of papers to be read and presented; it (the pamphlet) had already reached sixty-four pages, and the eleventh section, that of Ophthalmology, was not concluded, there being six more sections to be included, so that it would be impossible to give a fair idea of the material preparing without taking up a great deal of space.

So far, 338 foreign delegates are on the list as having expressed their intention of being in attendance.

The general sessions will be held at Albaugh's Opera House, which is centrally located on Fifteenth Street, just below Pennsylvania Avenue, and looks out on the grounds of the President's House and Washington Monument. It ought to be cool and well ventilated. Its seating capacity is about thirteen hundred, including the balcony seats; the floor, comprising what is known as the orchestra and orchestra circle, seats seven hundred and eighty. The stage is moderately large, and the acoustics are pretty good. The Sections have also been provided with suitable accommodations.

The programme for the meetings is about as follows:

Monday, September 5. General meeting at Albaugh's Opera House, beginning at 11 A.M. Forenoon: Organization of the Congress, report of Secretary-General, report of Chairman of Local Committee, Address of Welcome by Secretary of State Bayard, Address by the President of the Congress, and other addresses. The Sections will meet at 3 P.M.

Tuesday, September 6, 10 A.M. General addresses: First, Dr. Austin Flint, of New York, on "Fever: Its Causes, Mechanism, and Rational Treatment." Second, Dr. Mariano Semmola, of Naples, Italy, on "Bacteriology and Its Therapeutical Relations. The Sections will meet daily from 11 A.M. to 1 P.M., and from 3 P.M. to 6 P.M.

Wednesday, September 7, 10 A.M. General addresses: First, Dr. P. G. Unna, of Hamburg, Germany, on "The Relations of Dermatology to General Medicine." Second, Dr. G. Fielding Blanford, of London, on "The Treatment of Recent Cases of Insanity in Asylums and in Private Houses."

Thursday, September 8, general meeting at 10 A.M. General Addresses: First, Dr. A. Luteaud, of Paris, on "The Influence of Discoveries of American Surgeons on the Development of Gynecology in Europe." Second, Dr. Neudörfer, of Vienna, on "The Military Medicine of the Present and that of the Near Future."

Friday, September 6, general meeting at 10 A.M. for general business.

Saturday, general meeting at 10 A.M.; adjournment.

Although, as stated before, it is impossible to do justice

to the material to be presented at this meeting, I cannot avoid noting a few papers on interesting subjects accompanied by the names of prominent medical men from abroad. Thus, in the section on General *Surgery*, William MacEwen, of Glasgow, Scotland, will read a paper on "Brain Surgery." Edmund Owen, of London, has two papers on "The Surgery of the Hip-joint; Paracentesis of the Articulation in the Early Stages of Disease of the Hip-joint," and "The Distention of the Capsule in Disease of the Hip-joint." Dr. Ollier, of Lyons, has a paper on "The Results of Resection in an Orthopedic and Functional Point of View." Dr. Leon Le Fort, of Paris, on "Gradual Dilatation of the Urethra." Neudörfer, of Austria, has several papers to present, dealing chiefly with problems in military surgery; he is Sanitary Chief of the Fifth Army Corps. Sir Thomas Longmore has a paper on the soldier's equipment for field dressing of wounds in time of war. Dr. Joseph Ewart, of London, has a paper on "Cholera," and Dr. Frederick Esmarck, of Kiel, a paper on "Field Dressing of Gunshot Fractures of the Lower Limbs in Connection with Transportation."

In the Section on *Obstetrics*, Prof. Emil Ehrendorfer, of Innsbruck, Austria, has a paper on "Puerperal Fever." Dr. Thomas More Madden, of Dublin, one on "Puerperal Septicæmia." Dr. M. Sänger, on "Conservative Cæsarean Section." Kirch, of Italy, on the same. Dr. Goelson Duncan, of London, gives a case of Porro's operation, and Prof. Lazarewitch, of St. Petersburg, a new normal (?) forceps. Lawson Tait has also a paper on "Tubal Pregnancy."

In other sections we note a paper by Prof. Rosenthal, of Vienna, on "Experimental and Clinical Observations of Cocaine." Dr. D. Hack Tuke, of England, on the "Care of the Insane." Dr. John Battey Tuke, of Edinburgh, on the "Legal Relation of Epilepsy." A paper on "Massage," by Dr. Charles Weber, in the Section of *Therapeutics and Materia Medica*, one by Dr. G. Ludvic Hirschfeld, of Paris, on the "Inefficacy of Ferruginous Injections," and one on the "Poison of the Cobra," by Dr. T. Gnezda, of Berlin. Dr. Dudley Wilmot Buxton, of London, gives "Experimental Studies in Asphyxia." In *Otology*, Dr. B. Loewenberg, of Paris, has a paper on the "Treatment of Tinnitus Aurium." In *Anatomy*, Reginald Harrison, of Liverpool, on the "Bladder;" Dr. William Mitchell Banks, of Liverpool, on the "Wolffian Bodies." In *Diseases of Children*, Dr. E. Bouchut, of Paris, on "Tubage of the Glottis." In the Section of *Dermatology and Syphilography*, are papers by Mr. Jonathan Hutchinson, of London, Dr. P. G. Unna, of Hamburg, Dr. T. Colcott Fox, of London, and several other well-known foreign dermatologists. The Section on *Public and International Hygiene* is favored with papers by Thudichum, of London, Antoine Magnin, of France, Tommasi Crudeli, of Italy, Domingas Freire, of Rio Janeiro, Benjamin Ward Richardson, of London, Mapother, of Dublin, and others.

Unfortunately for the entertainment of the Congress, September is an unsatisfactory month, especially in Washington; as very few private citizens or government officials remain in the city during that month, so that comparatively few houses will be thrown open. The clubs have taken, so far, no active part in preparing for entertainments, and the usual visit to the public buildings, Corcoran's Art Gallery, and a trip to Mount Vernon, will about comprise the list. The new Pension Building, a vast structure, in an out-of-the-way place, looking like an old-fashioned factory of some kind, old-fashioned, because modern factories are built with some idea of appearances, has a fine space enclosed within its walls which will be used for the banquet. The trip to Mount Vernon will be made by the foreign guests on a man-of-war, placed at their disposal by the Secretary of the Navy. The other delegates will be taken at reduced rates on the regular steamer. On Sunday, September 11th, a special train will take the foreign guests, by way of Watkins' Glen, where a stop will be made of twenty-four hours, to Niagara Falls.

The cards of invitation have been prepared, and present some interesting features. The banquet card has on its back a succession of leaves from an artist's portfolio, depicting the Landing of Columbus, Birthplace of Washington, Signing of the Declaration of Independence, Surrender of Cornwallis at Yorktown, called "The Peace of 1783," Goddess of Liberty on Bedloe's Island, Grand Army Review in Washington in 1865, Inauguration of Governor Cleveland. On the other side are the words "The Committee of Arrangements Appointed by the American Medical Association have the Honor to Invite," etc. The Niagara Falls invitation has, as a centre view, the Horseshoe Falls, then panels showing Watkins' Glen, Seneca Lake, High Bridge, New York, and Washington City. The Mount Vernon invitation has a very excellent view of the house and tomb.

The Assistant Secretary of the Treasury, Mr. Maynard, has ordered the admittance free of customs duties of articles, books, instruments, etc., imported in good faith for the Congress, and not intended for sale. The Secretary General has forwarded a list of the delegates for this purpose.

WASHINGTON, D. C., August, 1887.

A DAY AT MOORFIELDS EYE HOSPITAL.

Moorfields is the Mecca to which all foreign ophthalmic surgeons find their way when visiting London. Founded as a special hospital in 1804, it grew rapidly into notice as a school for ophthalmic surgery under the guidance of John Cunningham Saunders, who first adapted the operation for cataract to the condition of infancy. Moorfields has always been famous for its staff of brilliant operators; probably the most brilliant was George Critchett, who died quite recently. To-day, Mr. Lawson is quoted as the dextrous surgeon—Mr. Couper the authority on refraction and the inventive genius of the institution, Messrs. Morton and Lang authorities on retinoscopy, Mr. Gunn the authority on obscure retinal affections, whilst Messrs. Hulke and Tweedy are the scientists. The enormous yearly attendance is startling, one sees gathered together a wealth of clinical material not found elsewhere, and to the student who is able to make examinations and appreciate this wealth the field teems with rich returns.

The number of attendances of 25,863 new patients (1886) has been 123,475. The in-patients admitted to the wards for operation have been 2118.

Opportunity is now given young men to study ophthalmology under the instruction of such able men as Messrs. Lang, Gunn, and Silwek, younger members

of the staff who have done much to advance this Institution as a medical centre.

Mr. Tweedy, the senior surgeon of the day, brought before the notice of the visiting physicians many interesting and striking cases :

Case 1.—Man, sixty years of age, who had been operated upon for cataract; the vitreous was fluid and in making the incision the lens became dislocated down and into the vitreous; by a slight quick stroke on the lower part of the globe the lens was returned to its place, it was then removed with a scoop. Inflammation of the iris followed, leaving a closed pupil. Inasmuch as the vitreous was fluid, Mr. Tweedy selected a small sharp-pointed knife which he passed through the cornea at its outer margin, and by gently passing the knife through the iris at its inner attachment was enabled to make a horizontal incision through its whole width without the loss of any fluid. The wound gaped widely and a good oval pupil was the result, good vision was expected. The after-dressing was atropia and cold compresses.

Case 2.—A patient who presented himself with symptoms of acute glaucoma. After an operation to relieve tension the eye rapidly grew worse, and to-day the eyeball was removed. Upon examining its interior a large sarcoma of the choroid was found. Upon the removal of an eyeball a sponge which has been thoroughly disinfected in a sublimate solution is pressed into the socket over the upper lid, and this held in place by a pressure-bandage—after six hours the first bandage is removed and a second sponge reapplied—absorbent cotton, saturated with sal-alembroth, is placed in the orbit. This cotton is antiseptic, prepared in a solution of perchloride of mercury and the chloride of ammonium.

Case 3.—Needle operation for recurrent capsular cataract. The point of interest in these operations is the use of the incandescent electric lamp. The room is made absolutely dark, then with the aid of a strong condensing lens the rays of light, which are intensely brilliant, are focussed on the eye—this renders the opaque lens capsule brilliantly white, which enables the operator to lacerate the capsule without difficulty, as the depth of the anterior chamber is the more easily measured by this procedure. The after-treatment is iced cloths for twelve hours.

Case 4.—Iridectomy after an injury, without cocaine. The surgeon held the eye fixed in position; with his left hand he grasped the entangled iris, which was cut off by the assistant. Atropia and cold dressings comprised the after-treatment.

Case 5.—Woman, fifty-one years. Iridectomy for acute glaucoma. Eserine was applied, but gave only temporary relief; as vision was rapidly failing, an iridectomy was resorted to. The operation was performed skilfully, making a large scleral wound with a narrow Gräfe's knife and excising a large piece of iris; some hemorrhage followed. Mr. Tweedy anticipated a good result.

In giving an anæsthetic the Moorfields surgeons "start" the patient (young or old) on chloroform following with ether—some surgeons prefer nitrous oxide gas followed by ether. No case of accidental death has as yet followed the "administration of these mixed anæsthetics."

Case 6.—Iridectomy for chronic glaucoma in a man fifty-three years. No remarks.

Case 7.—Removal of an incarcerated iris following a wound in the cornea produced by bursting of a ginger ale bottle. After-treatment atropia solution grains iv to ℥j, and cold applications with slight pressure-bandages.

All instruments used about an operation are disinfected in a solution of the bichloride of mercury 1 to 5000. After the removal of the iris it was found that traumatic cataract had developed which would be treated as the exigencies of the case required. Atropia solution and cold applications suggested.

Case 8.—Burow's operation for trichiasis. The upper lid was everted over a horn spatula and an incision made through the cartilage about two lines from the margin of the lid—this opening is made wide enough to admit the point of the scissors blade, which is passed forward beneath the tarsal cartilage and the orbicularis muscle inward, in two sweeps of the scissors the cartilage is severed—in like manner the outer half is cut. The narrowed opening is by this operation made wider and the eyelashes pushed forward, giving the patient great relief—usually one operation brings permanent relief. The operation may be repeated. Belladonna lotion dressings applied. No reaction generally follows.

Case 9.—Cataract operation on a patient sixty years old. The Moorfields incision, which is a semi-flap, was made, the iridectomy large—followed by a peripheral laceration of the capsule—the lens was easily delivered and the patient counted fingers at once. The eye was dressed in a style peculiar to Moorfields. First patent lint disks, upon which a coat of vaseline has been placed, are put upon the closed lids, over this absorbent (antiseptic) cotton—a light woollen bandage holding all in place, after twenty-four hours the dressing is renewed —in ten days the patient is allowed his freedom. By following this treatment but two per cent. of fatal cases occur, while it places the patient in more unpleasant surroundings—living in constant darkness for ten days —the English (London) surgeons do not like to change for the "rational method of treating cataract operations" now resorted to by the advanced ophthalmic surgeons on our side of the water.

Case 10.—Mr. Lawson followed by first bringing to our attention a unique case that he had operated upon ten days ago. The patient suffered from a marked congenital deformity of the upper left eyelid (coloboma), the cleft extended to the upper attachment of the lid, exposing the eyeball. It was not only unsightly, but the globe was constantly irritated by this exposure. The margins of the cleft were denuded, following this a vertical incision was made, one inch in length, extending from the outer canthus vertically, this allowed the cleft to be brought in apposition by silk sutures; the outer wound was subsequently brought together in like manner. The after-treatment consisted in the constant applications of lead water and laudanum. The result was all that could be desired.

Case 11.—The removal of a mature cataract in a patient sixty years old. The operator passed a knife through the anterior chamber, bringing its point out directly opposite its point of entrance—the withdrawal was made in one sweep, making a typical Gräfe incision. Mr. Lawson attributes much of his success in cataract operations to this movement of his hand; where many

to and fro movements are made the lips of the wound are serrated, and in consequence its perfect coaptation interfered with, allowing too much drainage, and preventing healing by first intention; microbes also finding an easy entrance. The iridectomy and delivery of the lens was perfect. The after-treatment did not vary from that described above.

Case 12.—Traumatic cataract in a man fifty years old. This was a particularly interesting case. Two weeks ago a small piece of steel penetrated the cornea, rupturing the lens capsule, producing a traumatic cataract. It was thought that the steel had buried itself in the interior of the globe,-which would eventually produce panophthalmitis, or engender danger to its fellow. The lens was first to be removed, to ascertain the location of the foreign body. A free corneal flap was made upward, followed by an iridectomy. In removing the iris, it was found that the lens was soft and pulpy; by slight pressure the lens matter was forced out, and with it came a piece of steel about one millimetre square; a clear black pupil was obtained, and the patient counted fingers. A good result was prognosticated.

Case 13.—Boy, aged twelve years, with proptosis of the left eyeball. This case is being watched with considerable interest, as the supposed cause of the displacement of the globe is due to an ivory exostosis. Nothing was done.

Case 14.—Was operated upon for convergent strabismus. The subconjunctival method was applied. The conjunctiva, which was rendered insensible by an application of a two per cent. solution of cocaine, was seized over the insertion of the internal rectus, a horizontal incision one centimetre in length, made through the conjunctiva and Tenon's capsule. The muscle was then elevated by passing a hook through this opening and underneath the muscle, with one snip of the scissors the muscle was detached. The tissues surrounding the insertion of the muscle were freely separated. The after-treatment was simple dressing. A full correction of the visual defect was made prior to the operation. In squints less than two lines, the visual defect is corrected; if this correction fails to remove the convergence, an operation is performed after six months, above this defect an operation is performed at once, plus the visual correction. The double tenotomy is rarely performed at the same sitting.

Case 15 came under the charge of Mr. Couper. The patient, a woman, fifty-two years old, had *immature* cataracts in both eyes, *vision equalled* $\frac{10}{CC}$ in each eye. The knife was passed through the cornea without the usual forceps fixation; after the removal of part of the iris, the anterior portion of the lens capsule was grasped with a Forster's forceps and detached, the lens delivered without difficulty. Since the introduction of Forster's method of removing the anterior half of the lens capsule, Mr. Couper has had a lesser number of recurrent capsular cataract operations to perform. Mr. Couper makes the following dressing: First the lids are thoroughly anointed with boracic acid ointment, followed with a covering of the above described antiseptic cotton-wool, over all a knit wool bandage, this bandage renewed in twenty-four hours; after one week, dry dressings made. The patient is tested for glasses after three to six weeks.

Mr. Couper called attention to the fact that he does not hesitate to remove *immature cataracts*, an experience dating over eight years gives him encouragement to continue.

Case 16.—Ten days ago the patient, a boy, aged seven, presented himself, having lamellar cataracts, and was operated upon at once by the needle method; to-day the soft lens substance was removed by suction, leaving the pupil clear. Before the introduction of Bowman's syringe, the nucleus of the lens was distinctly seen in the anterior chamber, looking hard and firm. It was broken to pieces by the action of the suction, and entered the mouth of the instrument without difficulty. Atropia solution and iced compresses constituted the after-treatment. The solution used in the suction instrument was one to twenty of carbolic acid.

Case 17.—Subacute glaucoma. An iridectomy performed four weeks ago, but at intervals tension increased to plus three, during this period paracentesis was performed. To-day the seventh operation was made. Tension disappeared at once. Sclerotomy may be resorted to. The after-treatment *nil.*

Case 18 demonstrated the value of large probes in dilating strictures of the lachrymal duct. Under this treatment the patient has been doing well—the epiphora has almost entirely disappeared.

The above series of cases will give your readers a correct idea of the average amount of surgical operations performed daily. In the out-patient department nearly three hundred cases were counted, suffering from all grades of disease from simple hypermetropia to inflammations of the most violent type.

L. WEBSTER FOX.

NEWS ITEMS.

THE HYGIENE OF SUMMER RESORTS.—The necessity for the enforcement of proper precautions in the sanitation of hotels, dwellings, and villages which are occupied during the summer only, is forcibly shown by the following case in point, as given in the *Sanitary Engineer* of August 6, 1887:

Another instance of criminal carelessness and ignorance has been brought to light in the matter of the drainage and water-supply of a summer resort—a condition of things for which the proprietors should be held pecuniarily responsible in damages for the sickness resulting, and criminally if fatal results ensue. Investigation at the Conanicut Park Hotel, near Providence, R. I., where an outbreak of fever resulted in an abandonment of the house by the guests, showed that the well was situated under the floor of a room adjoining the laundry; two earthen drains, with the usual leaky joints, passed within a few feet of this well, making a junction just beyond it, so that the well, with considerable ingenuity, was located just within the angle, in order that every possible facility might be afforded for its receiving the contents of these leaky drains. A removal of the floor revealed a mass of filth from the drains running into the well. Of course, the business of this hotel for this season is practically killed. The question, however, which is of importance, now is, How many other summer resorts have their wells or drinking-water cis-

terns in close proximity to drains now defective or likely to become so?

The Providence *Journal* says the Rhode Island State Board of Health has no funds to enable it to make the necessary inspections of such resorts. If this is true, it is to be hoped that such will not be the case another year, and as a measure of protection every State Board of Health should endeavor to secure legislative authority and funds to make such inspections, and also to prepare a plan showing the drainage system of all summer hotels, including location of wells, cisterns, and cesspools, all to be drawn to a scale. A copy of this plan, certified to by State health authorities, should be required by law to be conspicuously posted in each summer resort. There is now sufficient intelligence in these matters outside the keepers of such establishments to detect and cause the correction of any serious defects; publicity, therefore, would be an effective safeguard.

It is quite as important in these days that such information should be posted for the information of the public as that certificates of boiler inspections should be displayed on all steam vessels. Indeed, we believe polluted water destroys more lives than steam-boiler explosions.

Bleeding in Sunstroke.—At the Chambers Street branch of the New York Hospital, a patient suffering from sunstroke who had a temperature of 108.8° and had had violent convulsions for twelve hours, was recently bled to the extent of eighteen ounces, with the effect, apparently, of saving his life; although twice afterward the temperature went up as high as 105°. A case very similar in character which was brought to the same hospital some time since, and in which bleeding was not resorted to, terminated fatally.—*Boston Medical and Surgical Journal*, August 4, 1887.

The Illinois State Board of Health.—The Illinois State Board of Health did a piece of work at its last meeting which required courage. Under the new law they are permitted to grant licenses to itinerant venders of medicines for a fee of $100 a month. At its meeting there were eight applications for such licenses, backed up by powerful political influence, which would have brought in $800 each month into the board's coffers. They were all denied licenses, however, though to an outsider, it looks like heroic application of the law.—*Sanitary News*, August 13, 1887.

Bromidia.—The United States Circuit Court has granted a perpetual injunction restraining Gross et al. from manufacturing or selling any medical preparation under the name of "bromidia" or any colorable imitation of it.

The Cholera.—Three fatal cases of cholera are officially reported as having occurred this week at Malta. The authorities appear to be doing what they can to prevent the spread of the disease by removing suspicious cases to the lazaretto, and by thoroughly cleansing out the houses. In consequence of the existence of the malady on the island, quarantine is imposed at Gibraltar and Madrid on vessels arriving thence. At Catania the disease during the last week has not, it appears, diminished in violence, from fifteen to twenty deaths being recorded daily. The disease has extended to the prisons and monasteries. In the provincial towns (especially at Anderno, Paterno, Francofonte, and Cerami) the epidemic seems on the increase, whilst more favorable reports come from Syracuse and Calabria. According to a recent telegram from Bombay, cholera prevails to a serious extent at Peshawur, where 300 deaths occurred from the disease during July.—*Lancet*, August 6, 1887.

Laryngology in Berlin.—The new Laryngological Clinic under Dr. Fränkel is now in full work, and is attended by a large number of patients. It is fully recognized by the authorities as a place for study, being replete with every instrument and convenience.—*Lancet*, August 6, 1887.

Broca's Statue has been recently taken from the Salon and erected at the corner of the boulevard Saint-Germain and the street of l'École-de-Médecine.

The Individual Bath in Public Hygiene.—Dr. Rohé is quoted as follows upon this subject by *Science* of July 15, 1887:

Public, like private, bathing institutions, must make provision for individual baths. Large pools, in which many persons bathe at once, fail to answer the requirements of sanitary science or of public decency. A French army surgeon, Duval, has overcome this difficulty, and now both the French and German soldiers have proper facilities for bathing. The latter are required to bathe every week, the government furnishing the bath-room, warm water, soap, and towels. In our army and navy no steps have been taken to introduce this reform, although Dr. Billings has shown its feasibility. Dr. Lassar, of Berlin, has demonstrated the practicability of separate bath-rooms in connection with public bathing, and has been urging the extension of the military system to the civil population, so that every German may have his weekly bath. He gives excellent illustrations of the practical benefits to be derived from the adoption of such a system. At the white-lead works in Ehrenfeld, the eighty employés are required to bathe weekly, the facilities being furnished by the proprietor. In the first year, 1884, the sickness was reduced twenty per cent., and in 1885 it was reduced still lower, fifty per cent. In certain dye-works in Berlin, ten rooms, containing shower-baths, have been provided for workmen and their families, and for all who desire to use them. In Göttingen, with a population of 21,000, of which number 3000 are children who attend the public schools, baths are fitted up in the basement of one of the schoolhouses. A class of fifty can bathe in an hour. Each child has the opportunity of bathing once in two weeks, and seventy-five per cent. of the children avail themselves of it. The authorities and teachers are unanimous upon the point that the system is of great benefit to the children, not only from its direct sanitary advantage, but from the habits of cleanliness formed, to which they are likely to adhere through life. The only cities in the United States having public baths are, Boston, with 17; New York, 15; Philadelphia, 5; Brooklyn, 3; Cleveland and Hartford, each 1; and Buffalo, the number not given. In New York, 3,431,086 persons bathed from June to October in 1883; during the same time in Boston, 959,763; and in Brooklyn, 225,885. In eighteen

cities where there are no public baths, only about twenty-three per cent. of the residences are supplied with bath-tubs.

PELLAGRA IN ITALY.—This disease has assumed serious proportions in Italy. It is attributed to the poor bread commonly used, and has affected the inhabitants of the provinces of Lombardy and Venetia with especial severity.

The bread is coarse, ill made, badly baked, and fresh but once in five days; it can not be digested by the stoutest stomach.

The government is preparing new quarantine and preventive laws against the disease. In the Exhibition of Millers and Bakers at Milan, the products of infected districts were marked by cards of warning. In the last five years numerous hospitals have been opened for those afflicted with pellagra; but its ravages among the very poor have been extensive.—*L'Abeille Médicale*, June 13, 1887.

ARTICULATED AND SIGN LANGUAGE.—When we wonder at the rapidity with which deaf-mutes spell out their words on their fingers, we are apt to feel that this invention has really diminished the disadvantages of this class of persons almost to a minimum. That such is not the case is vividly suggested by the statistics which a teacher of the deaf-mute has had the patience to gather. He has counted the average number of words which a pupil in his school wrote or spelled on the fingers per day, and finds it to be 1118; the teacher similarly employs 216, but uses signs equivalent to 861 words daily. It has been estimated that a mother talks 27,000 words to her child in a day. Making due allowance for the habit of forming only parts of sentences which the deaf-mutes cultivate, and also for the suggestiveness of the sign language which hearing people really also use in the form of an expressional accompaniment), the comparative meagreness of the deaf-mute's conversation and slowness with which his mental food can be brought to him, are plainly evident.—*Science*, July 8, 1887.

A NEW WINE.—A Frankfurt (German) firm has produced a wine made from whortleberries which has been extensively tested and examined by German chemists. Its percentage of alcohol is less than that in grape wines, and its purity has led to its use in the army and navy, and its quality and refreshing taste have led to its introduction into a number of hospitals.

THE IRRIGATION SYSTEM OF DISPOSING OF SEWAGE.—The irrigation system of sewage disposal has been greatly extended in Germany. In Berlin it has given great satisfaction, the sewage of 900,000 people being carried to irrigation fields, and the water which drains off being submitted to chemical examination for evidences of pollution, which were discovered but once during an entire year. The objection that this system of sewage treatment is not applicable in cold climates is invalid, as is shown by the results in Pullman, Ill., and in Dantzig, Germany. Birmingham, England, with a population of 600,000, has adopted the irrigation system, and the income realized during 1885 from the sale of stock and produce from the sewage farm, amounted to over $100,000.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM AUGUST 16 TO AUGUST 22, 1887.

BAXTER, J. H., *Colonel and Chief Medical Purveyor.*—Ordered to proceed from Washington, D. C., to New York City, on public business, and on completion thereof to return to this city.—*S. O. 187*, par. 5, *A. G. O.*, August 13, 1887.

BAILY, JOSEPH C, *Lieutenant-Colonel and Assistant Medical Purveyor.*—Granted leave of absence for one month.—*S. O. 191*, par. 10, *A. G. O.*, August 18, 1887.

WOLVERTON, W. D., *Major and Surgeon* (Washington Barracks, D. C.).—Granted leave of absence for twenty days.—*S. O. 174*, par. 3, *Division of the Atlantic*, August 16, 1887.

TREMAINE, W. S., *Major and Surgeon.*—Found incapacitated for active service by an Army Retiring Board, and extension of leave of absence on account of sickness still further extended until further orders.—*S. O. 192*, par. 9, *A. G. O.*, August 19, 1887.

BYRNE, CHARLES B., *Captain and Assistant Surgeon* (Washington Barracks, D. C.).—Granted leave of absence for one month, with permission to apply for an extension of one month.—*S. O. 174*, par. 4, *Division of the Atlantic*, August 16, 1887.

DIETZ, WILLIAM D., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, with permission to apply for an extension of one month.—*S. O. 189*, par. 7, *Headquarters of the Army, A. G. O.*, August 16, 1887.

MCCAW, W. D., *First Lieutenant and Assistant Surgeon.*—Relieved from temporary duty at Fort Riley, Kansas, and ordered to his proper station, Fort Leavenworth, Kansas.—*S. O. 84*, par. 3, *Department of Missouri*, August 15, 1887.

JOHNSON, HENRY, *Captain and Medical Storekeeper.*—Ordered, in addition to his present duties, to take charge of the office and perform the duties of Acting Assistant Medical Purveyor in New York City, during the temporary absence on leave of Lieutenant-Colonel Joseph C. Baily, Assistant Medical Purveyor.—*S. O. 191*, par. 11, *A. G. O.*, August 18, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR TWO WEEKS ENDING AUGUST 20, 1887.

LONG, W. H., *Surgeon.*—Leave extended six days on account of sickness, August 13, 1887.

FESSENDEN, C. S. D., *Surgeon.*—Leave extended thirty days, on account of sickness, August 19, 1887.

GODFREY, JOHN, *Surgeon.*—Granted leave of absence for thirty days, August 17, 1887.

GLENNAN, P. H., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, August 18, 1887.

MCINTOSH, W. P., *Assistant Surgeon.*—Granted leave of absence for twenty-five days, on account of sickness, August 17, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 20, 1887.

ROBINSON, S., *Medical Inspector.*—Placed on Retired List.

GARDNER, J. E., *Passed Assistant Surgeon.*—Detached from Naval Hospital, Norfolk, Virginia, and ordered to the Fish Commission Steamer "Albatross."

MARTIN, WILLIAM, *Assistant Surgeon.*—Ordered to Naval Hospital, Norfolk, Virginia.

VAN REYPEN, W. K., *Surgeon.*—Appointed Medical Inspector from August 16, 1887.

SIMONS, M. H., *Passed Assistant Surgeon.*—Appointed Surgeon from August 16, 1887.

PAINLESS TIC OF THE FACE.

TREATMENT BY FREEZING WITH RHIGOLENE SPRAY.

BY S. WEIR MITCHELL, M.D.,
MEMBER OF THE NATIONAL ACADEMY OF SCIENCE.

THIS local affection of the muscles of the face supplied by the seventh pair of nerves, or by some one of its branches, has interested me at different times of my clinical life, and I have, at various periods, sought to treat the malady by as many forms of medication, but always in vain. Recently my attention has been re-directed to the matter in consequence of my having seen three cases of facial tic, and having been so fortunate as to cure one of them, and to relieve another.

Naturally one looks to the cause of a disorder of this kind for aid in directing methods of treatment, but the causes spoken of by authors such as Ross, as influenza, tumor at the base of the brain, aneurism of the vertebral artery, inflamed glands in the vicinity of the stylo-mastoid foramen, abscesses of the parotid, caries of the temporal bone, etc., have none of them ever furnished me with an example of painless tic due to direct irritation of the facial nerve in some parts of its course. Localized tic of some of the muscles of the face, I have, of course, seen as a rare result of intracranial disease. Neither have I seen it as due to reflex irritation conveyed by the fifth nerve, and, although I have searched every case with care, neither carious teeth, nor irritations of the eye, nor disease of the antrum have enabled me to connect any of them with facial tic as cause and effect. I have, it is true, twice seen painful neuralgia of the face converted into neuralgia with painful tic, and ending in a cure of the neuralgia, but leaving a persistent painless tic. I have also seen spasm of the sterno-cleido-mastoid extending by degrees until it produced a unilateral convulsive spasm of the face. But this seems to be clinically distinct from what is ordinarily known as painless tic.

The symptoms of the clonic form of facial spasm of which I am now speaking have been over and over again described, but there remain, nevertheless, some points in connection with this disorder which I do not see spoken of in the descriptions given by the various authors who have written on this subject.

I find in my note books records more or less complete of nine cases: Five existed on the left side alone, two on the right side alone, and two were found on both sides, but I think it is more common than these numbers would indicate to find it existing on both sides. The affection is, of course, far more violent in some cases than in others. It may vary from the slightest twitching of the eyelids, in which such twitchings are almost a normal phenomenon, so frequent are they in nervous people, to the most extreme excursions of the large muscles and skin on one side of the face, occurring at intervals of a few seconds, or some minutes, and in certain cases being frequent during the day, in others coming in sets of spasms, so to speak, lasting for twenty or thirty minutes, or for one or two hours. In all of my cases these spasms ceased during sleep, and commonly did not recur until some little time after the patient had passed out of that state. I have once seen a case of these paroxysms originating at each attack with pain, of which Ross speaks as an occasional thing.

I have traced with care in some of my cases the onset of the attacks in individuals intelligent enough to have noted and remembered how they started. In nearly all in which I could obtain a history the spasm seems to have originated in the muscles around the eye or under the eye, and to have spread thence through the other muscles of the face. It has been usually observed that these actions do not damage volition except during the actual occurrence of the convulsive acts. In some of my cases of extremely violent spasm the facial lines on the side affected seem to have been deepened. In two cases, at least, apparently not differing from the others, there was undoubtedly some slight defect of voluntary power on the side of the spasm, and the face exhibited that curious peculiarity sometimes seen in slightly paralyzed persons where, when they smile the smile begins on the sound side and follows a little more tardily on the other. The most careful examination has never revealed to me any sensory changes as to touch on the side affected by tic. Nor have I in a single one of the general cases of tic been able to suppress it by pressure on any of the points at which nerves emerge or elsewhere, as may so often be done in that peculiar form of facial spasm which affects the lids, causing a long-continued closure, such as indeed may endure for weeks. Since my attention has been redirected to this subject, I have examined also the electric conditions of the muscles on both sides of the face in people affected on one side, and have observed, in two instances at least, a far more ready response to induction currents on the side attacked by spasms than upon the other.

I have never had the good fortune to see one of these cases at its outset, and probably few have been called to treat it at that time, since commonly it begins with some slight twitching, as I have said, around the eye, and extends thence to other muscles of the face and is not seen by the physician for treatment until it has become quite extensive enough to be a source of anxiety or annoyance.

Facial tic of the type now under consideration is apt to be increased by moderate emotion, as meeting strangers and becoming conscious of observation. Extreme emotion will occasionally suspend it, as it will the wildest local chorea, of which I have elsewhere related a striking case. It is, I think, unnoted in the classical accounts, that in some cases mastication, deglutition, laughter, or talking are competent to cause attacks in persons affected with tic. I observed, also, that the first jet of rhigolene spray caused a violent facial spasm in two of my cases. In some tic patients walking brings on an attack, and any violent motion does the same.

If we conceive of a motor face centre as in a state to discharge energy at any moment, and needing but the least irritative contribution to cause spasm, we shall have a fair mind image of the state of things described. The act of speech, mastication, laughter, all motion in fact, all emotion, the sudden chill of rhigolene, give rise to overflows of nerve energy which sweep over the whole nervous system, and contribute enough added stimulant to excitable centres to occasion spasmodic action in related muscles.

This seems to me to be the mechanism by which we may explain the action of motion, sensation, and emotion in bringing on the attacks of tic in persons subject to it. Like overflows seem to be able to reinforce already irritated sensation centres so as to cause pain, because in trigeminal neuralgia mastication, speech, and laughter seem all to be capable of suddenly bringing on pain fits.

As one of the curiosities of the subject, I may add that the disease is sometimes suspended by a grave, intercurrent malady—as pneumonia—and sometimes cured as by typhoid fever. It has been my lot to see many bad cases of tic, of some of which I have kept notes, but I have never cured, or greatly aided, a case of long standing which was not due to hysteria.

I have never been forced to stretch the facial nerve as a remedy, but have seen an example of perfect success in a patient of my colleague, Dr. Sinkler. The operation by Dr. Wm. W. Keen was done more than three years ago, and to-day there is no trace either of paralysis or of spasm. There are, however, many reasons why people shrink from this somewhat serious operation, and there are varieties and mild forms of the disorder in which one naturally hesitates to resort to the knife. Dieffenbach's operation, in which he divided subcutaneously all the muscles affected by spasm, seems to me to be a method which should not be allowed to go out of use, as he is said to have had with it good success. For my own part, I have used all the ordinary remedies mentioned in the books, but have failed with one and all.

A few months ago I saw in a middle-aged lady a case of unilateral facial spasm, which set me to thinking afresh whether I might not be able to relieve her, and it then occurred to me that it might be possible to lessen the conductibility of the facial nerve by other means than stretching it, and that if I could freeze it where it spreads out on the face I might effect some good in this disagreeable malady. A little reflection, or, indeed, the use of my own memory, would have told me that with the means employed I should not be able to freeze so deeply as to produce what I expected, a congestion of the nerve I meant to freeze.

By placing a finger within the cheek and freezing the outside with the spray, it is easy to discover, as I myself found, that the deepest freezing possible with rhigolene does not extend through the thickness of the cheek, so that my expectation of thus directly affecting the nerve was futile, and any explanation founded upon a belief that the nerve was frozen must be laid aside. Whatever effect I did produce—and it will be allowed that it was somewhat interesting and remarkable—must have been due to a quite superficial freezing, and probably to reflex effects exerted through the trigeminus.

The first case in which I employed this agent was that of Mrs. B., aged sixty. The lady applied to me on November 4, 1886, the victim of a painless tic of the right face, which occurred at intervals, and had lasted for four years; never absent for more than half an hour of the waking day, it returned in spells, which persisted a few seconds at a time, and repeated themselves about fourteen times in a minute, after which there was apt to be a period of rest. The excursions of the face were most extreme, and seemed to affect all the muscles of the face so as to distort it for a time, closing the eye on that side in a most inconvenient fashion. Absent during sleep, it returned within an hour after waking, and, like neuralgia of the fifth nerve, was apt to be brought back or increased by the acts of talking, laughing, or eating. The lines of the face on the side of the spasm were a little more deeply marked than on the other, and the faradic reactions were distinctly better. She was somewhat sallow, but her blood count showed no marked anæmia, and, except an occasional trace of albumen in the evening, her urine was without casts. As to the cause of this unpleasant malady, I could not even make a reasonable guess; nor was there in the state of her teeth, her eyes, or her general health anything which explained it. I should add, as regards the spasm, that it was not capable of being reinforced by distinct muscular acts, nor did it seem to me, though of this I was not sure, to be competent to reinforce the knee-jerk.

After using the spray for the first time, she returned the next day, telling me that for two hours after its use there had been no spasm of the face. After five sprayings, on successive days, the face ceased to make any violent movement, the spasms became less and less severe, and, after fourteen applications, were confined entirely to the muscles around the eye, which ceased now to close that organ convulsively. At this time, having satisfied myself of the value of the local remedy used, I began to give tincture of chloride of iron internally, and malt extracts for the purpose of improving general nutrition. After twenty freezings had been used on successive days her condition was so satisfactory that she declared the spasms rare even under the eye, not more than a dozen times a day, when usually their recurrence could be traced to the act of mastication, or, at all events, to eating. She

was now absent for seventeen days, and, on her return, exhibited no change for the worse. For a few days the freezing was renewed, when I again allowed her to abandon the spray, as she declared herself entirely satisfied with the result, even if no larger good were gained. I directed her, on her return home, to apply ice and salt to the face daily over the region of the *pes anserinus*. This, however, made her face so very sore that she had to poultice it at one time, and, after twenty applications, at various intervals, she abandoned the use of this form of cold.

On May 2d, of this year, she returned to me in very good condition, certainly very much improved in general health and appearance, and with so small an amount of spasm as to satisfy her that no further treatment was necessary. I advised, however, that the spray should be applied by her physician thrice a week, but as long periods had elapsed without any form of application of cold, it seems probable that we may reasonably expect her to remain relieved. This case was valuable to me, and interesting because it was the first time I had, in a large experience, succeeded in relieving a facial tic.

In the second case, that of a lady, aged sixty-nine, I was less fortunate, perhaps because the malady had lasted so long. It began in 1878, under the left eye, and extended thence without pain or numbness. It was growing worse, and occasionally of late awakened her in the morning, and was now especially apt to recur with increasing violence if she was tired from any cause; talking and eating both seemed to provoke attacks. When she first applied to me she was rarely free from spasm for more than fifteen minutes at a time during the waking day. Her attacks occurred, as a rule, every two or three minutes. They were large spasmodic movements, enduring about fifteen seconds, during which time the face was drawn violently to the left, the lids quivered with a fine tremor, and there was a complete closure of the left eye, which happened, unfortunately, to be by far the better organ of the two. There was a slight extension of the spasm to the skin and muscles of the neck on the left side. The facial lines were less distinct on the left, the right eye was myopic and astigmatic, but competent correction had not at all relieved the spasm.

In this distressing case rhigolene spray was used assiduously seventeen times. No better effect was obtained than so far to lessen the spasm as to prevent, up to this time, the constant closure of the eye during the attacks. Beyond this I could see no gain, although she herself, and her family, insisted that the attacks were rather less frequent and less violent.

I should have preferred to wait for other opportunities before publishing the successful result of a single case; but painless tic, severe enough to seek aid, is rather rare, and I, therefore, give this example without claiming for the spray any more than what is here set forth. No doubt others will test its value, and we shall soon know if mine was, for some reason, but a mere piece of good fortune.

A word as to the method of using the spray. Rhigolene is by far the best agent, far better than ether, and it is possible that in sudden freezing we have a therapeutic means too much neglected. Used alternately with heat, it certainly is of value in neuritis, and certain neuralgias.

When employing the spray for tic, I use it over the expansion of the facial, and over the exit points of the fifth nerve. The reaction is intense, and the part sprayed remains deeply flushed. When it becomes sore, it is only needful to avoid the tender region for a day or two.

The nature of the influence thus exerted, and probably affecting most the sensitive nerve, is but a matter for speculation. It is some time after the spraying before the maximum effect is obtained in the way of lessening the spasm, and this fact reminded me of the interesting results obtained by freezing the skin in birds, when often ten minutes elapsed before the convulsive acts thus produced in birds were to be seen. No such extreme phenomenon follows the use of the spray in man or quadrupeds, but, without doubt, even in these surface freezing must profoundly affect the centres.

OBSERVATIONS ON THE ACTION OF STENOCARPINE,

THE NEW LOCAL ANÆSTHETIC AND MYDRIATIC.

By EDWARD JACKSON, M.D.,

ADJUNCT PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC.

After Koller demonstrated the possibilities of local anæsthesia as produced by cocaine, various other substances, as brucine, lewinin, and apomorphine, as well as other alkaloids closely allied to cocaine, were announced by different observers as possessed of somewhat similar powers. But all failed to make good their claims to consideration alongside of cocaine; the latest, drumine, having proved in the hands of others utterly destitute of the powers ascribed to it by its discoverer. The discovery has now been announced of an alkaloid, said to be obtained from the leaves of a tree common in Louisiana; which certainly equals, and perhaps surpasses, cocaine in its power to abolish the sense of pain in the part to which it is applied.

The story of the discovery is, that Mr. M. Goodman, V.S., having applied to the fetlock of a horse a poultice made, by chance, of these leaves; subsequently made a free incision into the part without eliciting any evidence of pain. He furnished some of the leaves to Dr. Allen M. Seward, who obtained therefrom an alkaloid, a two per cent. solution of which caused local anæsthesia in the eye of a cat. Some of this solution was placed in the hands of Dr. J. Herbert Claiborne, who found that it produced anæsthesia in the eye of the rabbit and of man; also of the mucous membrane of the nose, and of the skin. That it produced wide dilatation of the pupil, and in some cases a diminution of intraocular tension, and slight dulling of the sensibility of the tympanic membrane. Dr. Claiborne published an account of the drug, and the results obtained from its application, in the *Medical Record* of July 30, 1887.

After this Dr. H. Knapp experimented with it,

applying the same solution to the mucous membranes of the eye, nose, throat, urethra, and rectum, producing anæsthesia in all of them. Hypodermatically it produced local anæsthesia of the skin, and a drop applied to the glans penis had the same effect; but in Dr. Knapp's hands external application to the healthy skin gave uniformly negative results. This I shall refer to presently. The injection of it into the cellular tissue of rabbits caused "violent attacks of tetanoid convulsions in which opisthotonus was a prominent feature," recurring every ten to forty seconds, for some fifteen minutes, but followed by complete recovery within an hour. The amount of the solution thus used to produce these symptoms varied from five to twenty-five minims. Ten minims injected directly into a vein of a rabbit's ear caused fibrillary convulsions, or tremors, of the front part of the body, and death in ten seconds. "The picture furnished by these experiments bears the greatest resemblance to that of strychnine poisoning." But "chemical tests for the detection of strychnine," applied to the drug, "proved negative" (*Medical Record*, August 13, 1887).

After reading Dr. Claiborne's account of it, I obtained some of this two per cent. solution of the drug. It was clear, of a faint brown tint, and had a taste distinctly bitter, but nothing like the intense bitter of quinine or strychnine. A few seconds after its application to the tongue and lips there was a peculiar sensation of numbness precisely similar to that produced by cocaine, but more intense than that caused by the four per cent. solution of the latter drug. No application I have yet made to the human subject has produced constitutional symptoms; but not over four minims of the solution have been used in any one case.

One drop, a half minim, of the solution, was placed in my left conjunctival sac. It caused smarting more noticeable than any similar application of a four per cent. solution of cocaine, but still not severe, and passing off in a few seconds. Succeeding this there was the feeling of "stiffness," "dryness," or "coldness" of the lids, which cocaine produces, and immediately a notable widening of the palpebral fissure, as compared with that of the other eye. As soon as I could test it, within two minutes and a half, there was complete anæsthesia of the conjunctiva and cornea. I pinched up the conjunctiva with fixation forceps without any sense of inconvenience, but dragging so as to pull on the subconjunctival tissue still caused pain.

In 10 minutes such dragging caused no pain.

At 15 minutes the anæsthesia was still complete, and the pupil just beginning to dilate. The width of the centre of the palpebral fissure, was in the right eye, 10 millimetres; in left, 11 millimetres.

20 minutes. Anæsthesia less complete. Diameter of pupil, which was 3 millimetres to start with, is now, by the same light, 4¼ millimetres. Power of accommodation reduced from the normal, 8, to 7.50 dioptres.

30 minutes. Pupil in bright light 8 mm., in darkness 9 mm.

40 minutes. Anæsthesia nearly gone. Pupil fixed, 9 mm. in diameter. Palpebral fissure as before. Accommodation 5.50 D.

60 minutes. Anæsthesia entirely gone. Pupil unchanged. Accommodation 3.50 D.

85 minutes. Accommodation 2 D.

3 hours. Accommodation 0.50 D.

6 hours. Palpebral fissure as before. Accommodation 0.50 D.

12 hours. Pupil unchanged. Palpebral fissure still wider than the right, but the difference less than before. Accommodation 0.75 D.

24 hours. Palpebral fissure equal in the two eyes. Pupil in bright light 8 mm., in the dark 9 mm., contracts quite notably with strong convergence. Accommodation 3 D.

48 hours. Pupil 5½ mm. in light which makes the right pupil 3 mm.; dilating to 7 mm. in darkness. Accommodation 6.50 D.

3 days. Pupil under conditions mentioned above 4½ and 6½ mm. Accommodation 7.25 D.

4 days. Pupil 3¼ and 6½ mm. Accommodation 7.75 D.

5 days. Pupil still a little larger than its fellow; and accommodation perceptibly weaker than in the right eye.

6 days. Recovery complete.

Instillations of the same solution in the eyes of sixteen other persons, seven males, nine females, varying in age from five to fifty-two years have in every case caused the same anæsthesia; complete within one, two, or three minutes, and passing off mostly within a half hour. In all, the palpebral fissure was notably widened, the pupils widely dilated and fixed; and the power of accommodation very nearly, or quite, abolished by a single instillation. When the instillation was repeated the accommodation was always entirely abolished. When no other mydriatic was used, recovery of the accommodation and pupil was almost complete at the end of three days. That is, it had reached that stage where it is commonly spoken of as complete, and where its incompleteness cannot be detected except by comparison with the fellow eye kept in a normal condition. Dr. Claiborne speaks of recovery, in the trial made by him, as complete on the third day.

In three cases the drug was used to paralyze the accommodation, for the purpose of determining the refraction. In all it answered the purpose satisfactorily; and in one the subsequent use of duboisine revealed no additional hyperopia.

In four cases it was used simultaneously with duboisine (after the methods given for cocaine in my paper on that drug in THE MEDICAL NEWS of Aug. 27, 1887); in three cases it was so used with homatropine; and in one with hyoscyamine; and in all it caused a wider dilatation of the pupil, a dilatation very noticeably wider, than did the other mydriatic.

In no instance could I satisfy myself that it produced any change in the degree of intraocular tension; although I sometimes suspected it slightly decreased it. In no case did I perceive those corneal changes which I have noticed after the equally free use of a four per cent. solution of cocaine; and which are described in the paper above referred to. In these normal eyes, and in three eyes suffering from acute catarrhal conjunctivitis, there seemed to be less blanching of the conjunctiva than I would expect to see from the same use of a four per cent. cocaine solution.

Hypodermatically in the forearm one and a half grains of the solution caused complete insensibility of an area about four by eight millimetres in extent,

reaching mainly from the seat of injection toward the extremity of the limb. The anæsthesia was noticed instantly, but seemed to extend its area for about ten minutes. It disappeared in half an hour.

Applied externally to the skin it caused complete anæsthesia. This was tried four times on the flexor aspect of the forearm, and on the back of the hand. The method of application was simply to moisten the spot and keep it continually moist with the solution. The anæsthesia was very marked in ten minutes, but continued to increase slightly for half an hour. At the end of that time I could plunge a needle into the skin without the slightest sensation. In one of these trials on the flexor surface of my own forearm, at the end of ten minutes I commenced an incision; and keeping the blood wiped away and the surface continually moist with the solution, completed it within five minutes more, to the depth of three millimetres, without the slightest unpleasant sensation, either at the time or afterward. The healing was normal. In this respect my observations are directly opposed to those of Dr. Knapp, and in accord with those of Drs. Claiborne and Seward. I think Dr. Knapp's experience may be accounted for in one of two ways. First, the anæsthesia, although absolute, is in my experience very superficial. By plunging the point of the needle somewhat deeply, one may feel it pass from the layer anæsthetized into one in which it causes the usual degree of pain.

To make a painless incision in tissues anæsthetized in this way, one must do it by repeated superficial cuts with the knife, keeping all the time the cut surface bathed with the solution. Possibly, Dr. Knapp made his first incision or plunged his needle too deeply, passing into the underlying tissues still acutely sensitive. But it is more probable that he entirely prevented the absorption of the drug by preliminary treatment of the skin, adopted doubtless for the purpose of facilitating it. He washed the skin with soap and water. The writer tried washing the flexor surface of his forearm with soap and water, and then immediately applied the drug in the way above described. After half an hour no anæsthesia had been produced, although the surface was covered by the sticky residue left by the drying of the solution. The rationale of this is very simple, a portion of the free alkali of the soap probably remained adherent to the skin and promptly precipitated the alkaloid from the portion of the solution that came in contact with it. Such a solution is very sensitive to the action of a free alkali. The simple blowing upon this solution or a similar solution of cocaine, of air containing free ammonia, quickly renders it milky with such a precipitate. In the trial mentioned, when the solution of the drug had failed to produce anæsthesia at the end of the half hour, I stopped its application, and placed on the surface covered with its residue, a dilute acid solution, and in ten minutes had quite a notable anæsthesia.

Upon frogs this drug acts as a violent depressomotor poison; reflex movements continuing somewhat after the abolition of voluntary movements. In my first trial of the drug on the frog, I injected three-fourths of a grain of this solution into the subcutaneous tissue, and replaced the animal in water. It swam easily for an instant, stopped, drew up its limbs, and retracted its eyes a little, and in two minutes was to all appearances dead, except for a slight precordial pulsation, which continued for two hours. This frog weighed ninety grains. The relatively smallest fatal dose was one grain of the solution given to a frog weighing three hundred and ten grains. In four minutes it lay entirely relaxed, giving slight reflex movements. In five minutes no sign of life except the precordial pulsation, which continued for over two hours.

The largest dose required to produce death was two grains of the solution, for a frog weighing two-hundred and forty grains. Here, in half a minute there was diminished retraction of the eyes when touched. In fifty seconds its head had sunk down upon the table. At seventy-five seconds the last voluntary movement was noted. In two minutes reflex movement was abolished. The precordial pulsation was perceptible, and thirty per minute, at ten minutes, but soon after that ceased.

This same frog had previously recovered after receiving one grain of the solution. At that time there had been, in 1 minute, great weakness, cessation of all spontaneous movements, and inability to keep or regain the normal position of floating in water. In 3½ minutes, no breathing, no retraction of the eyes when touched, and very slight reflex movements on stroking. In 8 minutes, more marked reflex movements. In 15 minutes, good retraction of the eye and reflex movements on stroking. In 10 hours, quite well. It had also recovered after receiving four grains of a four per cent. solution of cocaine.

The action of smaller doses is shown in the following:

A frog, weighing 195 grains, received hypodermatically one-fifth of a grain of the two per cent. solution.

In 2 minutes it was notably weaker, and when laid on its back could not recover its position.

8 minutes. Lies flat on its belly; makes no movement spontaneously, and but little when smartly pricked. Retraction of the eyes and reflexes from stroking markedly lessened. Cannot keep position in water.

15 minutes. Reflexes better; more movement when pricked.

25 minutes. Its movements are much more vigorous, but not well coördinated. Cannot regain its normal position in water, but keeps it when once placed in it. Does not move spontaneously.

35 minutes. Recovers position promptly in water, but does not when laid on its back on the table.

70 minutes. Recovers position when laid on its back on the table.

10 hours. Apparently quite well.

In two "pithed frogs," one non-fatal and one fatal dose in each, the action was apparently the same as in the normal animal.

In every case, as in those above noted, in which the drug caused death, the heart continued to beat steadily, often for hours, after all other evidence of life had ceased. When, however, the chest was opened and the heart was bathed in the solution, its action immediately became slower, then more feeble, and presently ceased.

In studying the action of this drug, one cannot

but be struck with its similarity to that of cocaine. The sensations produced, the complete though brief anæsthesia, the widening of the palpebral fissure, the dilatation of the pupil greater than that produced by any other mydriatic except cocaine, and especially the general physiological action: in the frog, killing with symptoms of general motor paralysis, not ordinarily affecting the heart much, but slowing and weakening it when directly applied; and the tetanic convulsions in warm-blood animals, such as are caused by cocaine, and have been produced by that drug in man,[1] are all common to the action of both drugs. Even the anæsthesia of the skin I have produced, in nearly or quite equal completeness, with a four per cent solution of cocaine.

This similarity of action raised in my mind the question, whether this new drug possessed any power which would not be possessed by a solution of cocaine to which had been added a portion of one of the stronger mydriatics, as duboisine or hyoscyamine. It seems to me, however, from a careful review of my experience with it, that this drug does possess certain powers, in degree at least, peculiar to it. My impression, from my present experience, is that the solution used, said to be a two per cent. solution, is a more powerful anæsthetic than the four per cent. solution of cocaine. It certainly has a more powerful influence on the frog. The frog killed by two grains of this solution had withstood the action of four grains of the four per cent. cocaine solution. And in a series of some thirteen parallel experiments performed on frogs with these two drugs, cocaine always showed itself the less powerful. Yet this new drug has seemed to exert less influence on the local circulation and the nutrition of the cornea than cocaine.

Then, too, cocaine has but little power of paralyzing the accommodation, while this new anæsthetic-mydriatic has a much greater power in this direction. Still the recovery after the use of the new drug is more rapid than after any other efficient mydriatic, except homatropine, and it has a more powerful influence over accommodation than homatropine. The superiority of the new drug in this direction is especially manifest in its ability to overcome the influence of eserine. Thus the influence of cocaine on the pupil is overcome by one-fiftieth of its weight of eserine, and its influence on accommodation by still less.[2] Homatropine is neutralized by one-eighth its weight of eserine. But this drug requires two thirds or four-fifths of its weight of the myotic to overcome it.

If it is a local anæsthetic more powerful than cocaine, and a mydriatic more powerful yet brief in its action as homatropine, it must be a new drug, and one of great practical importance.

It will be noticed that I have persistently avoided calling this drug by the name which has been given it by Dr Seward, and this has been because I do not believe it is the name by which it should be finally known. Speaking of the origin of the drug, Dr. Claiborne says:

"Mr. Goodman informs me that the tree is known in the locality mentioned as the Tear Blanket Tree. It grows to the height of thirty-five or forty feet, with a diameter to the bole of about eighteen inches, and a spread of foliage of about thirty to thirty-five feet. The leaves resemble those of an acacia. The bark is smooth. From the ground up the tree is furnished with clumps of forked spines or thorns, the parent spine springing at right angles from the bough or trunk. As fruit it bears pods eight or ten inches in length, flat and slightly curved, containing seeds and a viscid juice. The spines are very tough and highly polished, and the wood is extremely tough. It grows in clumps and singly, and is abundant in Louisiana. From the likeness of the tree to the *Acacia stenocarpo*, Dr. Seward dubbed the new alkaloid stenocarpin."

In Professor Charles S. Sargent's "Report on the Forests of North America," vol. ix. of the *Reports of the Tenth Census of the United States*," I find no such tree as the *Acacia stenocarpo* mentioned; and it is not conceivable that a common tree yielding a valuable wood should have entirely escaped notice. Mr. Goodman's description of the tree, however, corresponds closely with that of the *Gleditschia triacanthos*, or common Honey Locust, which grows plentifully in Louisiana, and in many other parts of the United States. Extracts made from the leaves of the honey locust growing near Philadelphia, however, have failed to exhibit any anæsthetic or mydriatic properties. Another member of the same genus, *G. Monosperma*, the Water Locust, which is also common in Louisiana, may possibly be the tree in question.

So while it is pretty certain that the source of this drug is not a tree known to botanists as the *A. stenocarpo*, it remains very uncertain what that source is. On that question, and on the chemical constitution and characteristics of the alkaloid, more light is much to be desired. Enough has been learned of its physiological action to indicate the directions for therapeutical experiment, and we must now look to further clinical experience to fix its proper position and ultimate value.

THE ORIGIN AND HISTORY OF THE EPIDEMIC OF TYPHOID FEVER AT MT. HOLLY, N. J., DURING THE MONTHS OF JUNE, JULY, AND AUGUST, 1887.

BY ALBERT R. LEEDS, PH.D.,
CHAIRMAN OF THE COMMITTEE OF ANALYSTS OF THE STATE BOARD OF HEALTH OF NEW JERSEY.

Mt. Holly is supplied with water from Rancocas Creek. The water is not taken directly from the creek, but from a mill-race, as shown in the accompanying map. When the mill runs, water flows through this race; but when, after the day's work is over, the mill stops, the flow is interrupted also. The crib of the pumping-station is located in an angle or cul-de-sac of this race, so as to stand outside of the current.

From the crib two iron conduits, one of ten inches and the other of twelve inches, and 350 feet in length, with a fall of four inches in this distance, connect with the pump-well. The well is four and a half by eight feet, and four feet in depth. It is not separated

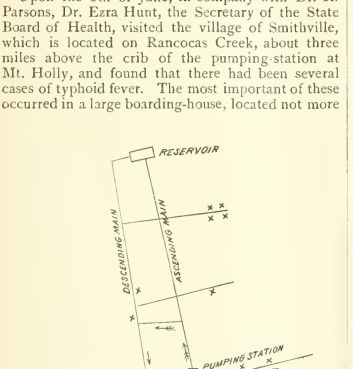
[1] Two cases by S. T. Earle, Maryland Medical Journal, March 19, 1887.

[2] See "Influence of Cocaine on the Pupil and Cornea," before referred to.

from the crib by any arrangement of filters or screens.

Prior to the time of my visit of inspection, but several weeks after the epidemic began, the mud which had accumulated at the bottom of the crib and pump-well was removed, and the crib was built out a distance of ten feet, so as to project its open end into the current. The sides were closed in and the open end covered with a grating having a three-eighths inch mesh.

Upon the 6th of June, in company with Dr. R. Parsons, Dr. Ezra Hunt, the Secretary of the State Board of Health, visited the village of Smithville, which is located on Rancocas Creek, about three miles above the crib of the pumping-station at Mt. Holly, and found that there had been several cases of typhoid fever. The most important of these occurred in a large boarding-house, located not more



than one hundred feet from the side of the creek, and emptying therein by three drains. Early in May there had been two men, who subsequently recovered, ill with typhoid, and at the time of Dr. Hunt's visit, Mrs. A. L. was convalescent of the same disease. The dejecta of all three had passed, without disinfection, directly through the drains into the creek.

In addition to these drains, the cesspools are located on the sloping grounds of the village, and their contents eventually wash down and are carried into the creek. Dr. Brown, the sanitary inspector of the township, reported that these cesspools had been disinfected with copperas and chloride of lime in the latter part of May, and the origin of the epidemic is more directly traceable to the discharges from the drains above alluded to.

From the 20th to the 27th of May there were heavy rains, and the epidemic broke out shortly afterward in Mt. Holly.

As will be seen by the accompanying map, the water was not pumped first through the ascending main into the reservoir, but at the time of the epidemic much of it passed directly into the distributing system.

The most striking collection of cases (indicated on the map by x), were those at contiguous houses supplied from a "dead-end" on Pine street.

At the time of my second visit to Mt. Holly, July 23d, Drs. Parsons, Parry, Barrington, Brown, and Melcher gave me the following list and details of cases up to that time:

On Pine Street, Case L. P. began June 20th; still very ill. W. W. began June 25th; disease still progressing. Cases D. S. and M. G.; the last, however, being properly gastro-enteritis.

On Ridgway Street there was another dead-end connected with a school. Four boys attending this school, though living in different parts of the town, were attacked with typhoid about the 2d of June, of whom one died.

On Mill Street there had been four cases, beginning from the 2d to the 5th of June, of which one proved fatal, on the 20th of June, and the others had recovered or were convalescent.

On Washington Street, M. C., after an illness of two and a half weeks, had died of typhoid. On Main Street, L. H. was attacked June 18th and died July 10th. On Church Street, L. D. was attacked June 6th. The record also includes other cases, beginning from the 1st to the 18th of June.

I am also in receipt of a number of valuable communications from Drs. Parry, Parsons, and Barrington, from which I shall take the liberty to quote.

Dr. Parry writes, July 20th: "I would call your attention to the part of the creek where the water was taken from, a sort of *cul de sac*, where the water never has a running current on the side or near the edge where the box is. It is virtually standing water while the mill is not running below, and hence a place where the sediment from up the stream must settle to. Add to this much mud in the crib and pump-well, a dirty reservoir to pump into, and polluted water, as this was shown to be, and we find it followed by the following cases, occurring about seven to nine days after a rain had commenced. . . . . All of these cases have taken more or less hydrant water, some using it entirely, some at the places of work, and some occasionally. Two-thirds of these cases have occurred, I think, from the 30th of May to the 10th of June. . . . In many cases there has been a very rapid pulse, with comparatively low temperature, some lower even than the above record. But in one case that proved fatal, the axillary temperature attained 106°, and registered above 104° daily for a week preceding her death, with pulse from 130 to 140 during the same time. . . . We have had, occurring at the same time as cases quoted, children afflicted with gastro-intestinal fever, not typhoid, but temperature, pulse, and duration of the disease the same as well-marked typhoid cases, with many cases of mild continued fever, and have had no malarial trouble in surround-

ing malarial districts, and these cases were not controlled by quinine, but all have had much gastric trouble, vomiting, etc. . . . . We have had in the last week or two, in addition to a few cases of typhoid fever, a dysenteric trouble with, in some instances, violent gastric disturbance."

Under the same date, July 20th, Dr. Parsons writes: "I have had under my care three cases of typhoid fever. These cases had the rose-colored spots, bleeding from the bowels and nose, and more or less stupor; temperature 102° to 104°, with a morning and evening variation of about 1°. Two of the cases used water supplied from the creek by the water company, the other used well water only when at home. I have also seen about twelve cases of fever which were remittent, but differing somewhat from the usual form by having some typhoid symptoms, and quinine seems to make no impression on them. This outbreak of fever occurred in various parts of the town almost simultaneously."

On the 23d of July I visited, in company with Dr. R. E. Barrington, the case L. P., and found it presented the well-known characters of typhoid fever. I took some of the greenish stools, and made some of the primary, secondary, and tertiary gelatine-peptone cultures from them. The predominant form was a nearly straight bacillus 0.006 of a millimetre in length, and 0.0002 of a millimetre in breadth, which in the third culture was obtained in a pure condition. The stools contained an innumerable quantity of these bacilli.

Although the data above narrated rendered the fact of this epidemic in Mt. Holly being rightly attributable to typhoid well nigh certain, yet I did not feel satisfied without the confirmatory evidence from autopsy. At my request, Drs. Parsons and Barrington kindly performed an autopsy, and under date of Aug. 8, the former writes: "You will receive by mail a section of the small intestine, and some fecal matter, taken from a patient six and a half years old. I made a post-mortem examination of this case on Saturday, August 6th. While the patient was very young, he had all the symptoms of typhoid, excepting the "spots," and died rather suddenly from intestinal hemorrhage. On examination, I found the ileum ulcerated in about a dozen places. This being the only autopsy during the epidemic, it establishes the fact that some of the cases are *true* typhoid."

Under date of August 15th, Dr. Parsons again writes: "The case from which the specimen was taken that I sent to you, was a child six and a half years old. He had continuous high temperature that varied from 102° to 104°, some slight diarrhœa occasionally, but no other abdominal symptoms, no delirium, very slight stupor, no epistaxis, loss of strength not marked. He improved very rapidly a few days before his death, so much so that the nurse moved him into another room. This brought on hemorrhage of the bowels from which he died in about eighteen hours, after a sickness of three weeks."

"At the autopsy I found in the lower part of the small intestine about twelve or fifteen ulcers, varying in size from a pin head to one inch in length. This ulcer had nearly perforated the intestine. There were several blood-clots and some fecal matter in the bowels."

I was deeply interested to discover what additional evidence of typhoid fever would be obtained by microscopic study of the material submitted by Drs. Parsons and Barrington. My attention was particularly directed to the sides of one of these typhoid ulcers in the small intestine, and after removing small portions of the adherent matter, I made a number of stainings with methyl violet. They all yielded me great numbers of micrococci, the micrococcus being mostly single, but many in short chains. According to Eberth, a certain bacillus with rounded ends is peculiar to typhoid, and Koch is of the same opinion, regarding this bacillus of Eberth as being the only one which has a specific relation to the disease. I find it likewise stated that when these bacilli of Eberth are present in great numbers they have the appearance of masses of micrococci, but when isolated from these masses they are recognized as short thick rods having rounded ends. Unfortunately, having no authentic specimen of Eberth's bacillus with which to compare my slides, I am unable to state whether or no what I took to be micrococci, were really Eberth's bacillus. They possessed one property which is the same as that of Eberth's bacillus, in that they were not so deeply stained by methyl violet as another bacillus present in the superficial layers of the intestine and in the fecal matter. This bacillus was a long, straight, thin rod which stained deeply, and which I took to be the bacillus typhosus of Klebs.

Having established by clinical and pathological evidence the fact that the disease in Mt. Holly was typhoid fever, it becomes of great interest to ascertain the character of the water which, whatever might have been the other surroundings of the typhoid cases, was the one food they took in common.

It would have been of great importance to take the samples of water during the period when the typhoid was incubating, say at the time when Drs. Hunt and Parsons visited Smithville on the 6th of June. But the opportunity of discovering whether the specific bacillus, which was found in the intestine of the typhoid cases, was also present in the water-supply during the period of incubation was lost.

The samples which I collected were taken on the 9th of July, at the time when much typhoid was prevailing in Mt. Holly, but probably subsequent to the inception of the disease in most or all of these typhoid cases.

I have made both chemical and biological analyses of the samples collected, the water on which the latter tests were made being obtained in sterilized flasks. Sample I. was from the Rancocas Creek above the village of Smithville, some 200 yards above the point where the three drains from the large boarding house entered. Sample II. was from the water as it entered the crib of the pumping station at Mt. Holly. Between the two points on both sides of the creek are three miles of meadow and marsh lands, the soakage of which enters the stream. Both

samples were dark yellow (No. 5 on my scale of water colors), of peaty taste and smell, and the sample II. was turbid with a great quantity of floating filaments of decayed vegetation. They contained:

I.—Above Smithville.

	Parts per 100,000.	Grains per Gallon
Free ammonia	0.002	0.0012.
Albuminoid ammonia	0.015	0.0087.
Oxygen required to oxidize organic matters	1.27	0.70.
Chlorine	0 45	0 26.
Hardness	3.10	1 80.
Total solids	6.30	3 67.
Mineral matters	3.30	1 92.
Organic and volatile matters	3.00	1.75.

II.—Pumping Station at Mt. Holly.

	Parts per 100,000.	Grains per Gallon.
Free ammonia	0.006	0 0035.
Albuminoid ammonia	0.0155	0 009.
Oxygen required to oxidize organic matters	1.10	0 64.
Chlorine	0.55	0.32.
Hardness	2 20	1.80.
Total solids	6.20	3.60.
Mineral matters	3.30	1.92.
Organic and volatile matters	2.90	1.68.

Chemical Data.

These data are conclusive as to the pollution of the creek waters by sewage at points below where sample No. I. was taken, which was *above Smithville*. It should be borne in mind that the analyses were both made on the waters after they had been allowed to stand until the suspended matters had settled, and the clear water pipetted off. The sample from above Smithville deposited very little, that from Mt. Holly much floating matter, this matter being evidently of vegetable origin. The clear waters thus obtained were both of the same deep tint of yellow color. Now it is very important to note that the gross amount of organic matters in sample I. was greater than in II. Moreover, the amount of oxygen required to oxidize the organic matters, and therefore the organic matters themselves, was greater in the Smithville than in the Mt. Holly sample. But that portion of the organic matters which was nitrogenous, was greater in the sample from Mt. Holly, the free ammonia and the albuminoid ammonia both being in excess. The free ammonia was three times more in the samples from the pumping-station. This fact, taken in connection with the corresponding increase in the amount of chlorine, is conclusive as to the entrance of sewage into the creek at or below Smithville.

Whenever the amount of peaty matter in solution is great, the amount of oxygen required to effect its oxidation is correspondingly high. This peaty matter is oxidized by contact with light and air both in reservoirs and in flowing streams, so that a stream which at its origin in cedar swamps is dark yellow in color, becomes nearly or quite colorless after flowing a number of miles. I do not think there is any ground for connecting the typhoid epidemic with this large amount of extractive peaty matter in the water supply. It was always present, and I have no reason for supposing there was any more in solution this June and July than at previous seasons. In fact the citizens of a town using cedar-swamp colored water ordinarily become advocates both of its taste and qualities. They are habituated to it, and it does not originate in them disorders of the stomach and bowels. When strangers come to the town, who are not accustomed to drinking water containing peaty matters in solution, and who do experience intestinal derangements attended with more or less diarrhœa, the citizens of the town are puzzled and indignant that these ailments should be connected with what to them is an entirely wholesome and satisfactory quality of water.

But what I desire to insist upon here is, that the typhoid epidemic was not due to the peaty vegetable matter, but to the animal matter in the nature of sewage which found its way into the stream, and whose presence was made evident by the chemical data. Fortunately we are not shut up to the consideration of these chemical data only in the present instance, but I am able to adduce also the results of the biological analyses, affording, as they do, overwhelming evidence of the fact of contamination by decomposable putrescent animal matters.

Biological Data.

I prepared gelatine-peptone cultures of samples I. and II., or rather those portions of these samples which were collected at the same time, but in sterilized flasks.

A. The plate culture of the Smithville sample yielded per cubic centimetre *50 colonies of bacteria.*

B. The plate culture of the sample from the pumping station yielded *8100 colonies of bacteria.*

Another plate culture was made by dipping a sterilized platinum wire in culture A and streaking with it a plate flowed with sterilized gelatine peptone. This streaked plate yielded 15 colonies, all of which proved to be Bacterium lineola, excepting one, which was Bacterium termo.

Another plate was similarly prepared from culture B. It yielded many colonies, which, on examination, proved to consist of Bacterium lineola.

Now it will be noted that I did not find in any of these cultures the bacillus of Eberth, or the bacillus of Klebs, or the micrococci of Chantemesse and Widal, which have been held by competent bacteriologists to be the specific pathogenic microörganisms of typhoid infection. What I did find were two very common species of the bacteria which flourish vigorously wherever putrefaction is going on. They are the so-called *scavenger* bacteria, whose beneficent function in the economy of nature is to prey upon the putrescent matter. They are the sharks of the biological kingdom. They live upon offal and sewage, and by transferring oxygen to such sewage through the medium of their vital processes, they break up and destroy noxious matter and convert it into simpler and innocuous substances.

Of these scavenger bacteria there were 160 times more in the sample at the pumping station than in that from above Smithville, and I know of no other

explanation of this fact than the presence of the sewage in the Mt. Holly sample, upon which they could feed and multiply.

Effect of Precipitation.

In connection with these bacteria I made the following novel experiment, and obtained therefrom a surprising result, and one of much sanitary importance. The practice of adding a minute quantity of alum to water in order to clarify it, is an old and very familiar one. But while it is successful in carrying down the dirt and coloring matters, I did not know what influence it would exert upon the bacteria. I therefore added alum, in the proportion of half a grain to the gallon, to the sample taken at the pumping-station. On standing, the peaty matter was entirely precipitated in reddish-yellow flakes, and the water above became perfectly colorless and clear. On pipetting off some of this supernatant water, I found that instead of containing 8100 colonies of bacteria per cubic centimetre, as it did before precipitation with alum, it contained *only 80 colonies*. They were all the Bacterium lineola.

On filtering some of this supernatant water through a double thickness of sterilized filter paper into a sterilized tube, I found no bacteria in the filtered water. In other words, the water had been rendered by the addition of an amount of alum so minute as to be inappreciable to taste and almost to chemical tests, *as sterile as if it had been subject to prolonged boiling*. I need not enlarge upon this demonstration, which, so far as I am aware, has not been hitherto made, of the possibility of completely removing all microbes from potable waters by the use of very minute amounts of alum followed by filtration. In case there is no organic matter in the nature of peat with which the alumina may unite, and, acting like a mordant in the operation of dyeing, may be precipitated as a lake, the alumina alone may be precipitated by the addition of lime or soda to alkaline reaction, and so carry down the bacteria. Or, in such case, a minute amount of a soluble iron salt like ferric chloride may be first added, and then after precipitation with soda or lime, removed together with the bacteria by filtration.

Recommendations.

The above results, and those obtained by personal inspection of the surroundings of Mount Holly, suggest three modes of obviating the danger of similar epidemics in the future.

I. Finding some point upon Rancocas Creek demonstrably free from sewage contamination. At present I know of none.

II. Finding a water-bearing stratum in the vicinity from which, by means of driven wells, an ample supply of pure soft water, which has been submitted to a natural process of filtration, can be obtained. This may be the most economical method, and some test-wells could readily determine.

III. Previous purification of the water by means of aëration under pressure followed by filtration. In addition to the purification effected by oxidation, a minute amount of alum might be employed, but it is probable that this would not be necessary. By laboratory tests I have already determined that this particular water could thus be rendered pure, colorless, and palatable to all persons. The results of these tests are also in accord with the practical operation of purification and aëration plants already established to treat, on a large scale, water supplies of similar character as that of Mount Holly.

Stevens Institute of Technology, Hoboken, N. J.

PRELIMINARY NOTE ON THE MEDICINAL USE OF THYMOL.

By FREDERICK P. HENRY, M.D.,
SENIOR PHYSICIAN TO THE EPISCOPAL HOSPITAL OF PHILADELPHIA.

Following the suggestion of Martini, in the *Annali Universali di Medicina e Chirurgia* for February, 1887, I have recently prescribed thymol in a number of cases of intestinal diseases, catarrhs, acute and chronic, and typhoid fever, with the result of convincing me that it is a valuable adjuvant to our treatment of such affections. I do not attach any particular significance to the fact that all the cases of typhoid fever, ten in number, to which I have thus far administered the drug, recovered; but my conviction that the course of the disease was most favorably modified by the treatment was shared by the resident physicians, by practitioners who visited the hospital for the purpose of seeing the cases, and last, and perhaps not least, by experienced nurses.

The benign course pursued by these cases was especially evident when contrasted with that of an equal number treated without thymol during the first half of my hospital term. The favorable effect of the drug was evinced by a steady descent of the temperature, by a gradual diminution in the daily number of stools, by the absence of mental excitement, and, most conspicuously, by the clean, moist tongue presented in every instance.

I have full notes and temperature charts of these cases, prepared by the resident physicians, Drs. H. C. Deaver and N. P. Grimm, but it is unnecessary to give the clinical histories, since they are identical with those of well-marked, but comparatively mild, cases of typhoid. One case caused some anxiety for a few days after his admission, on account of the presence of decided tympany and general abdominal tenderness, but these ominous signs gradually disappeared.

I have also administered thymol, with good results, to several cases of intestinal catarrh, of which one is worthy of some detailed account:

Mary S., æt. thirty-six, married, was admitted to the Episcopal Hospital on May 14, 1887. She was pale, thin, and anæmic. Seven years ago, after removing to Philadelphia from the country, she had an attack of "diarrhœa" (dysentery?), with from fifteen to twenty stools a day, in spite of treatment. Defecation was painful, with marked tenesmus, and the dejecta were thin and streaked with bloody mucus. Gradually the number of passages was reduced to from five to six per diem, and, for nearly seven years, notwithstanding treatment by several physi-

cians, this has been the daily average. Soon after admission she was given thymol gr. x., ter in die, and the next day the number of stools was reduced to three. A week later, she had a well-formed stool every second day, and expressed herself as feeling better than at any time during the past seven years. On July 1, when my term of service expired, she was well, so far as the diarrhœa was concerned, but was still somewhat anæmic.

The medicinal use of thymol is based upon its well-known antiseptic properties, and its action in the cases under consideration was favored by its great insolubility, which enables it to reach the intestine, mingle with its contents, and neutralize the toxic ptomaines that are formed in great quantity in catarrhs of the gastro-intestinal tract. In the opinion of many authorities, it is to the absorption of large quantities of these toxic products of fermentation and putrefaction that the so-called typhoid symptoms are largely due. These opinions do not rest solely upon theory, for it is found that, during the administration of thymol, phenol, which is one of the most constant products of intestinal putrefaction, and is almost entirely eliminated with the urine, is no longer found in that excretion.

I have always prescribed the thymol in pill, of which the best excipient is medicinal soap, and, so far, have not given more than thirty grains in twenty-four hours—two two and a half grain pills every six hours. This is a small dose, but I have seen no reason to increase it. This may be done, however, with perfect safety, and, perhaps, with still better results. It has been administered, with brilliant results, by Bozzolo, in cases of anchylostomiasis, in doses of from ten to twelve grammes (two and a half to three drachms) per diem.

The only case in which I found the drug to produce any unpleasant effect—slight digestive disturbance—was that of a woman with advanced phthisis, chronic diarrhœa, and who was, besides, the host of a tapeworm. Thymol has been found to be an excellent tænifuge by several Italian observers, and it was for this purpose that I prescribed it in the case last mentioned. The woman had voided no fragments of the worm for two weeks, and it was a question whether the parasite had been entirely expelled. Although but a few doses of the thymol were tolerated, they were quickly followed by the expulsion of several fragments of the worm.

Martini, whose experience with thymol has been large, has only found it to give rise to unpleasant symptoms—delirium and stupor—in one case, that of a girl, æt. fourteen, to whom thirty grains had been given in the course of two hours; the symptoms were transient, the treatment was resumed, and the case, one of typhoid fever, recovered without further mishap.

My colleague, Dr. D. J. Milton Miller, has continued the use of thymol in the medical wards of the Episcopal Hospital since he took charge of them on July 1, and, in reply to a recent inquiry of mine, writes as follows:

"Generally speaking, my success with thymol, in typhoid fever, has been most satisfactory. The cases do seem to run a more favorable course than usual, as shown by lower temperature-range, less diarrhœa, the absence of complications, and even a shorter duration of the fever."

In conclusion, it is my belief that the success obtained with thymol in the wards of the Episcopal Hospital renders the publication of this "preliminary note" not only justified, but imperative.

SIMPLIFICATION OF THE TECHNIQUE OF ANTISEPTIC MIDWIFERY IN HOSPITAL PRACTICE.

BY BARTON COOKE HIRST, M.D.
OBSTETRICIAN TO THE MATERNITY HOSPITAL OF PHILADELPHIA.

ANTISEPSIS in obstetrics may seem a subject already hackneyed, about which little more remained to be said, but even if the practice were universally adopted in the lying-in hospitals of this country, the technique, at least of antiseptic midwifery, might still be considered a matter worthy of further discussion.

In the most important contributions to the study of antiseptic midwifery in hospital practice that have recently appeared in this country, there is advocated a rather complicated system of preventive measures against puerperal sepsis, which might, perhaps, not always be easy of application. It is the object of this paper, on the other hand, to describe a more simple, and yet an efficacious plan, that is in use in the Maternity Hospital, and to dwell briefly upon the efforts that have been made to bring the general hygienic condition of the institution to as high a level as possible.

In common with many other hospitals where antisepsis is practised, bichloride of mercury is the disinfectant relied upon; its advantages over the biniodide of mercury, carbolic acid, thymol, and other agents, that have been recommended from time to time, have been so often set forth that it is scarcely worth while more than to mention its solubility, its cheapness, and, more than all, its destructive action, even in weak solution, upon the lowest forms of life when brought in contact with them, being excelled, perhaps, in this last attribute only by the biniodide of mercury. The solution of corrosive sublimate is prepared for use in the hospital by dissolving 128 grains of the salt in a quart of water; this solution is kept in the wards in dark-colored bottles until required for use, when an ounce, added to a pint or quart of water, makes a solution a very little stronger, respectively, than 1 : 2000 or 1 : 4000.

As soon as a woman falls in labor she is cleansed by a full bath, and is then taken to the ward, where she will be delivered, and will remain during the puerperium. As labor advances the patient is placed upon a bed, the mattress of which is completely covered by a gum cloth; upon this rests a clean undersheet, and over this again a rubber sheet, that well overlaps the mattress, and is laced down to the iron framework of the bed; upon this the woman lies, her buttocks resting on a piece of old blanket, some three feet square, that has been washed, soaked in a 1 : 1000 sublimate solution and dried.

As soon as the placenta is expelled, the blanket, soiled by the discharges of labor, is removed, an

earthenware bedpan is placed under the hips, and the patient then receives a vaginal douching of a sublimate solution, 1 : 4000, which is the only vaginal injection given during the whole course of the treatment in an ordinary case. The solution for the douche is held in a glass jar, supported, at a height of about six and a half feet, upon a wooden upright, and from the jar descends a rubber tube, provided near its lower end with a stopcock; to this is attached the vaginal tube, which is of glass, about a foot in length, suitably curved, perforated on all sides along that portion of it which remains within the vagina, when the tube is introduced as far as the cervix, but closed at its distal end, so that it is the vagina alone that is disinfected, an important precaution, we believe, against the possibility of mercurial poisoning from the entrance, retention, and subsequent absorption of the solution within the uterine cavity. These tubes, when not in use, are kept constantly submerged in a jar, filled with sublimate solution, 1 : 2000. Glass tubes, somewhat similar, although open, of course, only at both ends, and kept clean in a like manner, are used for giving rectal injections, which are administered with as much cleanliness as possible to guard against a possible infection from this source.[1]

The hands of all attendants, before coming in contact with the patient's genitals or buttocks, during labor, or in the puerperal state, are scrubbed with a nail-brush, in a sublimate solution, 1 : 1000. All instruments are cleaned in a carbolic acid solution, 1 : 20.

After the single vaginal injection has been given, the perineum, if lacerated, is repaired by a continuous catgut suture, and then the upper of the two gum sheets that have been described is removed, exposing the clean linen sheet underneath; under the woman's buttocks is now slipped a gum cloth, a foot longer than the width of the bed, and three feet wide, upon which rests a piece of blanket, like that which had been removed after labor, and upon this again is placed a piece of canton flannel, disinfected in a sublimate solution, 1 : 1000, and dried, as it presents a more comfortable surface to the patient's skin than would a piece of rough blanket. Canton flannel, blanket, and rubber cloths are removed three times a day, as long as the lochial discharge continues, and, at the same time, the patient's external genitals are wiped clean with a fresh piece of baked cotton dipped in sublimate solution, 1 : 2000. This practice constitutes a system of antiseptic midwifery that must commend itself for its simplicity, while its efficiency is attested by the adoption of a plan somewhat similar, although sometimes even more simple, in the maternity hospitals of Berlin, Munich, Buda-Pesth,[2] and in other equally well-known institutions. It will be seen that this system is based upon the belief that a woman during labor, or afterward, in the puerperium, is infected, if at all, by actual contact with the disease germs that are carried to her, and deposited upon an absorbing surface by the hands of the attendants or by the instruments that may be employed, and that she has little to fear from the atmosphere of a ward which is governed by proper hygienic rules, as long as the lochial discharges are frequently removed from the external genitals, where, exposed to the air, they might putrefy. Although impressed with the importance of non-interference with the parturient or puerperal female, as regards the use of disinfectants, should symptoms arise indicating infection along the parturient tract or the decomposition of retained membranes or fragments of placenta, an energetic course of disinfection is pursued. Intrauterine douches of sublimate solution, as strong, occasionally, as 1 : 1000, are given, and when the presence of decomposing material is suspected, the curette is employed. For the administration of a uterine injection, a Bozeman's canula is used, and to guard against mercurial poisoning, as the sublimate solution is about exhausted a quart or more of water that has boiled for two hours is poured into the glass jar of the fountain syringe, and flowing thence through the uterine cavity, it washes away any residue of the mercurial solution that might be retained and absorbed.

And now a word as to the efforts that have been made to surround each patient with as large a quantity as possible of fresh, uncontaminated air.

There are four wards in use in the hospital, with an average capacity each of 5750 cubic feet (the largest 6411, the smallest 5077), which allows each patient 1916 cubic feet of space, for there are only three patients at one time in a confinement ward, an extravagance of space that is not begrudged so long as it results in an economy of life. After three women have been confined in a ward, the third and last patient, as soon as she is able to leave her bed, is moved to the convalescent ward, when the doors of the confinement ward are closed, the windows thrown open, and the floors and walls well scrubbed, and no patients are admitted again until the other wards have been used in turn. The blankets that have been in use as part of the bed-clothing are taken with the patients to the convalescent ward, but, before being used again in the confinement wards, they are thoroughly washed and disinfected in sublimate solution. The bed sheets of the puerperal women are changed three times a week. The beds themselves are of iron, with a wire mattress upon which rests a corn-husk mattress; this latter is used for ten successive cases, and, although it has been well protected by a rubber sheet, is then destroyed, and replaced by a new one. After a case of septic infection the mattress has always been destroyed at once.

In order to secure sufficient ventilation in winter, —for in summer, with the doors and windows open, this problem presents few difficulties—the heated air that keeps the temperature of the wards as near as may be to 70°, is brought from without the house in large conduits leading to the furnaces, whence it goes directly to the wards above, so that none of the cellar atmosphere is forced up through the rest of the house, although the cellar itself has a water-tight cement floor, and is kept scrupulously clean. There enter each ward, on an average, 5000 cubic feet of

[1] Winckel: Path. u. Therap. des Wochenbettes, pp. 252–255. Hirst: specimen exhibited before the Philadelphia Obstetrical Society, April 7, 1887.

[2] Szabó: Arch. f. Gyn., B. xxx. H. 1.

this heated air every hour, while through the open fireplace—which is not used for heating purposes—there passes up the chimney, every hour, 6000 cubic feet of air, the extra 1000 feet entering the ward through chinks in the windows and doors, so that the atmosphere of the whole room is changed at least once every hour. The fireplace is provided with a sliding shutter to regulate the draught, which is sometimes excessive; while to increase the draught, should that be desired, a gas-jet is let into a small but deep alcove in the wall over the mantel-piece, connecting above directly with the chimney, and shut off from the room by a small glass door. The light from this burner is used as the night-lamp, and during the day, should one of the patients have an offensive evacuation of the bowels, by lighting the gas-jet the ward is freed from odor in a very few minutes.

A simple experiment showed what an effective ventilator this gas-jet can be: on a quiet summer day, with little air stirring outside, and no air forced into the room through the heaters, with the windows and doors closed, there passed up the chimney in an hour, 940 cubic feet of air. Under the same conditions, with the gas lighted, 1476 cubic feet of air passed up the chimney in an hour, an increase of more than fifty per cent.

It is customary in an article of this kind to support the claim for the efficacy of a method of treatment by showing its effect in reducing the mortality and morbidity. In this respect we have every reason to be satisfied, for although the clinic is not a very large one, and we are unable to present an unexampled number of consecutive confinements without a death, yet it must be remembered that the hospital was designed for the reception of a peculiar class of cases, unmarried girls, illegitimately pregnant for the first time, cases that constitute the severest test possible for any system. The patients come to us depressed in mind and body, having endeavored to conceal their condition by tight lacing; having, as a rule, attempted to bring on an abortion; often shunned by or shunning their family and friends, and as ill fit to resist the inroads of puerperal disease, should infection once occur, as any woman could well be. Joined to the liability of all primiparæ to infection, and the inability of this particular class of primiparæ to resist an attack of puerperal fever, there are the other dangers associated with primiparity: the liability to renal troubles and eclampsia; to lacerations of the vagina and perineum; to retarded labors demanding instrumental interference, especially in these patients of the Maternity Hospital, for the most part factory and shop girls, among whom there is a large proportion of contracted pelves.

In spite of all these disadvantages, however, from May 1, 1885, to May 1, 1887, there was only 1 death out of 220 confinements, a death-rate of 0.45 per cent. This death was due to sepsis, but it occurred before the thorough adoption of the system of antisepsis now in use. Since the last fatal case there have been 218 consecutive confinements without a death. In regard to the morbidity during the past two years, accepting 100.5° as the physiological limit to a rise of temperature after confinement, 24.1 per cent. of the patients have had fever, which lasted, on an average, two days. In 9 per cent. of the cases the temperature did not exceed 101.5°.

ELECTRIC CAUTERIZATION AND EVULSION OF MORBID GROWTHS ON THE VOCAL BANDS.

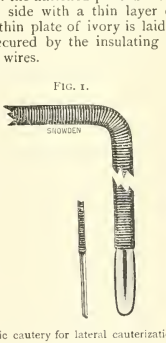
A PRACTICAL NOTE.

BY J. SOLIS COHEN, M.D.,
OF PHILADELPHIA.

THE interest at present evinced in the treatment of intralaryngeal neoplasms prompts me to present illustrations of two instruments successfully used by me in some difficult cases.

I. When a growth, located on the edge or lower surface of a vocal band, is to be attacked by the electric cautery, the platinum blade should be so guarded as to avoid injury to the sound side in the spasm likely to attend the cauterization. To accomplish this object the flattened platinum blade is covered upon one side with a thin layer of asbestos upon which a thin plate of ivory is laid, the whole being firmly secured by the insulating material of the conducting wires.

FIG. 1.



Protected electric cautery for lateral cauterization of the interior of the larynx, and especially of its morbid tissues at the edges of the vocal bands. (Actual size, lateral and front view.)

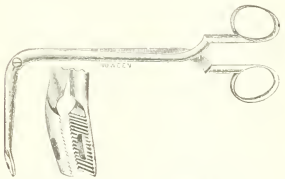
For similar lateral cauterization in the mouth, nose, or other passages, similar insulation of the blade often enables the operator to dispense with special shields for protection of the sound tissues.

It may be remarked here that an essential point in the construction of intranasal and intralaryngeal electric cauteries and the like, is not comprehended by the profession in general. This point is that the conducting copper wires of the electrode should be very thick. This confines the greater resistance to the current in the platinum terminal; and thus the body of the instrument does not become heated as it does when composed of thin wires. Only a certain amount of heat can be generated in a given instance; and this is wanted where it will be efficacious, and that is in the incandescent terminal, and not in the body of the instrument.

Wires too thick to pass a contracted nasal meatus can be flattened laterally, so as to present a smaller transverse section horizontally than vertically, without diminishing the bulk of the conductors. The shape of the conductor is unimportant, its bulk is all important.

II. A minute neoplasm seated upon the upper surface of a vocal band cannot readily be grasped with forceps having the ordinary olive-shaped blade. If the terminal of the blade is squared, however, as in Fig. 2, so many points of contact with the surface

FIG. 2.



Modification of Mackenzie's forceps, especially adapted to the evulsion of small neoplasms from the superior surfaces of the vocal bands. (Main figure two fifths size, jaws actual size.)

of the vocal band are secured that a very small growth can be caught and torn off with the blades of the instrument bent a little forward as shown in the illustration. I have removed growths no larger than hemp seeds, as well as growths much larger, situated upon the anterior portions of the vocal band. This instrument has been particularly valuable to me in the removal of cysts, and in ripping off thickened tissues from the vocal bands of vocalists. The blades of the forceps are applied separated to the surface of the vocal bands, and are maintained in contact with that surface during their closure, so that any prominence in their way becomes seized.

HOSPITAL NOTES.

PHILADELPHIA HOSPITAL.

AN ELBOW PRESENTATION DELIVERED BY SPONTANEOUS EVOLUTION.

(Reported by W. A. N. DORLAND, M.D., Resident Obstetrician.)

OWING to the advantages of operative obstetrics, the practitioner of to-day rarely enjoys the opportunity of witnessing the delivery of a transverse presentation entirely through the exertion of the maternal powers. Recently, however, the writer, being placed under peculiar circumstances, was present at the delivery of an elbow presentation by the process of *spontaneous evolution*. The history of the case was as follows:

C. G., aged twenty-six, II para, a native of Germany, was admitted to the waiting-room of the obstetrical department on June 13th. Fifteen days before admission, while carrying a roll of carpet up a flight of stairs, she fell eleven steps, alighting upon her face and striking her abdomen heavily, the carpet falling upon her. Up to that time the fœtal movements had been frequently noticed by her, but since then they had been entirely absent.

On June 20th, at 3 P. M., labor pains came on, and at 10 P. M. she was sent to the maternity wards. Auscultation revealed no fœtal heart sounds. On palpation a transverse position was determined. Upon making a vaginal examination the pelvis was found to be roomy, the os well dilated, the membranes ruptured, and the left elbow presenting. The ribs of the fœtus could be easily distinguished, as could also the lower angle of the scapula.

The rules of the institution not permitting the resident to perform version, the visiting obstetrician was immediately sent for.

The pains now becoming more frequent and quite severe, the presenting part was jammed tightly down, the arm and hand protruding from the vulva. These were soon followed by the shoulder and then the breech, propelled by violent pains, necessitating the administration of ether; and at 11.15 P. M. a macerated, full-term, male fœtus, weighing six pounds two ounces, was born, ten minutes after the arrival of the visiting obstetrician. The placenta was delivered simultaneously with the fœtus, the cord being twined three times around the neck. The duration of the labor was eight hours and a quarter, of which seven hours were employed in the dilatation of the os. There was no tear of the perineum, and no tendency to post-partum hemorrhage. The mother made a rapid and satisfactory recovery.

Beyond doubt, we think, the macerated condition of the fœtus and the roomy pelvis were important factors in aiding the propulsive efforts of the uterus.

MEDICAL PROGRESS.

SALOL IN THE TREATMENT OF INTESTINAL DISORDERS IN CHILDREN.—DR. GOELET, of New York, has had excellent results with salol and ice-water enemata, in intestinal disorders in children; he writes as follows:

While the adult dose is ten grains, the dose is much larger in proportion with children, and varies very considerably with the age. For a child six months old or under the dose is half a grain every two hours. From seven to ten months old the dose may be from one half to three quarters to one grain, according to the severity of the symptoms and the strength of the child. A child one year old may be given from a grain to a grain and a half, according to the severity of the symptoms. A child fifteen to eighteen months old may take a grain and a half to two grains. At the age of two years the dose would be two grains. For three years of age the dose would still be two grains to two grains and a half. Children of four years would require only two and a half to three grains, and those of five to six years would require only three or three and a half grains. And from this age to ten it is seldom necessary to give more than five grains. It is always given to commence with every two hours, and as the symptoms are relieved the interval is lengthened to three or four hours. As in the first case, I sometimes give it three or four times a day for twenty-four or forty-eight hours after the subsidence of the trouble.

The application of salol in bowel complaints is very

extensive. I have used it in all with the same pronounced success. In typhoid fever, every three hours, there is nothing better. While I cannot say that it shortens the attack, it relieves the excessively disagreeable odor of the feces and the tenesmus and flatulence produced by the accumulation of wind in the colon.

Diarrhœa and dysentery of children in summer are more promptly relieved by salol than anything else. Let me here outline a general course of treatment for these cases. To begin with, stop all food for twenty-four hours. If the little patient is thirsty, use a decoction of salep cold. This is made as follows: A salt-spoonful of powdered salep is rubbed into a paste in a cup with a tablespoonful of *cold* water and a pint of boiling water added slowly, stirring it all the while. This is set on ice, and, when *cold*, it may be given to the child almost *ad libitum*, but in small quantities at a time. Give the salol in appropriate doses every two hours until there is marked improvement in the bowels, and apply something warm to the abdomen. In the majority of cases the little patient will be ready for food in twenty-four hours. This should then be given in small quantities at first, and it must be of the proper kind.—*New York Medical Journal*, August 6, 1887.

Atropine for Sea-sickness.—Rebatel has obtained good results from the hypodermatic injection of atropine in small doses of a solution of $\frac{1}{2}$% of a grain to ʒ 2½ of water, repeated every 7 or 8 hours, until mild physiological effects are produced. The addition of a little morphia will often cause sleep in those who suffer from insomnia.—*L'Abeille Médicale*, July 18, 1887.

Collodion for Gouty Joints.—Monin advises the following:

Collodion. flex. . . .	} ãã 15 parts.
Ether. sulphur. . . .	
Acid. salicylic.	4 parts.
Morph. hydrochlorat. . . .	1 part.

For application externally about painful joints.
—*L'Union Médicale*, July 21, 1887.

Papain and Pepsine.—Finkler, of Bonn, thus compares the two substances on which he has made comparative experiments:

It is impossible to create in the stomach and intestines such amount of liquid as would be favorable to the effect of pepsine; the conditions, therefore, are very much in favor of papain.

Pepsine acts in the stomach but not in the intestines, as in the latter the reaction is neutral or alkaline. Papain has little effect in the stomach, as the reaction there is acid; when, however, the stomach is neutral or alkaline papain will peptonize, while pepsin will be useless. The degree of acid reaction in the stomach varies greatly, especially in the case of a stomach out of order, in which case the reaction can be so highly acid or alkaline that pepsine would be of no value at all. In the treatment of stomach catarrhs we will, moreover, find that as a general rule the contents of the viscus have been rendered artificially neutral or alkaline by the administration of remedies, so that in these cases pepsine will have absolutely no effect. Papain, on the contrary, will act energetically.

In the case o pepsine this is necessarily very short, as the action ceases when the food enters the alkaline reaction of the intestines. In the case of papain, which can act well in alkaline reaction, the time is practically unlimited, as it continues acting on the food during the whole time it remains in the body.

For all these reasons the conditions for the effect in the human body are far more in favor of papain than of pepsine, and especially as under existing circumstances (high degree of concentration) papain has been shown to act much more energetically; it is only too clear that the preference should be given to papain as a digestive ferment for the treatment of dyspepsia. Besides for dyspepsia, the papain is of great importance in the treatment of diphtheria. Its effective power consists in the circumstance that no free acid need be present in the application, and further, that the moisture of the diphtheritic membranes is quite sufficient to allow the ferment to dissolve the solidified substances of the membranes. No other ferment has so far been able to obtain these results. It is on this account that many competent experimentalists and specialists have lately made observations as to these points. From all these circumstances there is no doubt that in papain we have a ferment which has a great future before it, and it is for this reason that I have made a special study of the manner of preparing the papain. I have had the satisfaction of obtaining the most favorable results from its use in the treatment of disease.—*Lancet*, July 23, 1887.

Tetanus Successfully Treated by Cocaine.—Sober treated idiopathic tetanus with a solution of 5 to 100 of a mixture of hydrochlorate of morphia and hydrochlorate of cocaine. Three injections were made, and trismus diminished in two hours and the patient could move. Continuance of the treatment resulted in cure. —*El Genio Medico-quirurgico*, 1887.

The Persistent Virulence of Tuberculous Matter.—Galtier, at recent sessions of the French Academy of Sciences, has drawn attention to the dangers of the transmission of tubercular infection by the clarification of wines with fresh blood, derived from tuberculous animals. He further believes that neither heat, as ordinarily applied; drying; contact with water; the action of salt; freezing; nor putrefaction destroys the infective power of tubercle.—*Gazette Hebdomadaire*, July 8, 1887.

The Gonococcus in the Female Genitalia.—Steinschneider, of Neisser's clinic, in Breslau, has examined 57 prostitutes, finding in every case of gonorrhœa the urethra affected; in 47 per cent. the mucous membrane of the cervix uteri; in 50 per cent. the uterine cavity; occasionally, Bartholini's glands. In all recent cases the urethral secretion contained gonococci, whether scanty or profuse. Long after these germs disappeared from the urethral secretion they could be found in the cervix and uterine cavity, without visible inflammation. The vagina is not a good habitation for gonococci; either because its pavement epithelium is impervious, or its acid secretion destroys the bacteria, or because the great numbers of other bacteria destroy them.—*Annales de Dermatologie et de Syphiligraphie*, July 25, 1887.

THE ABUSE OF MILK DIET IN RHEUMATISM.—DR. BARTHOLOW writes as follows in the *Journal of Reconstructives* of July 12, 1887:

In no malady, as I conceive, is milk more abused than in acute rheumatism. It is very often the chief—sometimes the only aliment employed during the whole course of this disease. Besides the objection inherent in its mere bulk, certain theoretical considerations of its nature should have considerable weight in deciding the question of use. The very obvious objection that milk furnishes lactic acid as a product of its fermentation should not be ignored. All the world knows the intimate relation between lactic acid and the rheumatic poison. By the introduction of lactic acid, a form of endocarditis not distinguishable from the rheumatic, is set up, and of those diabetics treated by lactic acid, a considerable proportion suffer from attacks of rheumatic fever (acute rheumatism). It is difficult, of course, to determine this point with certainty, but I have reason to believe that patients with rheumatic fever do not get well so quickly, and are much more apt to have relapses when they consume much milk during the course of the disease. Surely, sufficient reasons exist for undertaking a thorough investigation of the question. My own practice, in the cases in which I am consulted, is to advise against the use of milk as an ailment in acute rheumatism.

THE PERCENTAGE OF STERILITY AMONG MEN.—KEHRER, of Heidelberg, has examined 96 men, as follows: Impotent, 3; having semen containing dead spermatozoa, 29; deficient spermatozoa, 11; excessive spermatic secretion, 53. The percentage of sterility is thus 33.32.—*Wiener Presse*, July 10, 1887.

NASCENT IODIDE OF SILVER IN CATARRHAL CONJUNCTIVITIS.—GROSELLI has used the following with advantage:

Argenti nitrat.	3.56 parts.
Glycerin.	6.50 parts.
Aquæ	3.50 parts.

Dissolve; filter, and keep in a colored flask.
Also,

Potass. iodid.	3.32 parts.
Glycerin.	6.50 parts.
Aquæ	3.50 parts.

Dissolve; keep in uncolored glass.

For use mix in a glass 2 drops of the first solution and 3 drops of the second. The lids are touched with the yellow precipitate which forms; they should be turned before the application is made.—*Gaz. Med. Italiana.*

A REMOVABLE WATER GLASS JACKET FOR SPINAL DEFORMITIES.—DR. BRUNS, of Jitomir, Russia, is quoted by the *London Medical Record* of July 15, 1887, as describing the following jacket:

A serious drawback of Sayre's jacket is that it cannot be taken off at will. The patient must constantly wear it for weeks, which often gives rise to pressure sores as well as (in pauper practice) to the appearance of numerous lice under the jacket; moreover, during the summer time the patient experiences a great inconvenience from heat, while bathing is impossible; any gymnastical exercise is also out of the question. To meet all demands, Dr. Bruns has invented a water-glass corset which may be easily taken off, while it is as solid as the plaster jacket, is not expensive (the materials required cost about five roubles, that is, about ten shillings), and may be prepared from the materials accessible to every practitioner. To make a corset for a child, aged from eight to ten, he uses 4 pounds of best, and 15 to 20 pounds of ordinary burnt plaster-of-Paris; then 3 or 4 pounds of water-glass, about 230 feet of linen roll-bandage, 6 or 7 small leather straps with buckles, strong threads, etc. Of instruments, only scissors, a knife, and a cobbler's awl are required. To obtain a cast, a thin Sayre's jacket is prepared. The weight of the apparatus, for a child, eight or ten, is about 3½ pounds. Up to the present the author tried his corset in two cases (in that of a boy, aged eight, with thoracic kyphosis, and of a girl, aged twelve, with intense scoliosis). The results (obtained from a six months' use) are said to be excellent.

PRECAUTIONS TO BE OBSERVED IN THE USE OF COCAINE.—DUJARDIN-BEAUMETZ is quoted as advising the recumbent posture during hypodermatic use of cocaine to avoid syncope. In twenty-four hours not more than seven and one-half grains should be given. Doses of one-seventh of a grain, repeated cautiously, are safest. The circulation of patients who are anæmic, or the subjects of cardiac or aortic disorders and liable to syncope, should be carefully watched.—*Journal de Médecine*, July 3, 1887.

ANTAGONISM AMONG BACTERIA.—GARRÈ is quoted by the *Deutsche medicinische Wochenschrift* of July 7, 1887, as reaching the following conclusions from a series of experiments. Inasmuch as pure cultures of bacteria do not grow extensively, but seem to be self limited, possibly by their own excreta, the experimenter mixed bacteria and their products, and found that the nutrient material was often so changed on the addition of a second that the first bacterium could no longer increase.

It was found that the *bacillus fluorescens putridus* of Flügge secreted an easily diffusible substance whose oxidation products colored gelatine green, and prevented the development of the Staphylococcus pyogenes aureus and the bacilli of pneumonia and typhoid fever. The reverse is not always the case in antagonism. Bacteria which grow in the same nutrient materials are called by GARRÈ symbiotisch. Examples of antagonism in the body are afforded by the destruction of cholera bacilli in water and other fluids by saprophytic bacteria. The same may occur in the intestine. The slow progress of periostitis of the jaws is an example of antagonism by the mixture of the staphylococcus with other germs. Garrè concludes that preventive inoculation is not to be made by bacteria of the same, but of unlike kinds, to those against which protection is sought; there is a possibility of successfully combating infectious diseases by prompt inoculation with appropriate bacteria.

NOTHNAGEL'S TREATMENT OF TYPHOID FEVER.—The *London Medical Record* of July 15, 1887, quotes a lecture by NOTHNAGEL, of Vienna, as follows:

In the treatment of acute infective diseases the great point is to search for so-called specific remedies. In quinine we have a drug which renders the malarial

poison innocuous, and we know that mercury and iodine destroy the syphilitic bacilli without destroying the organism. Of all the drugs recommended as specifics for typhoid, not one has stood the test; even calomel, when given from the very commencement of an attack, only seems to shorten the disease, but does not cure it directly. Calomel acts in two ways—first, it is a purgative, and helps to remove the bacilli from the intestinal canal, but castor-oil is quite as beneficial in this sense; secondly, calomel is a most powerful parasiticide, but it has not yet been proved to be a specific for the poison of typhoid fever. The only treatment, therefore, remaining is to treat symptoms as they arise. There are three indications met with in every case: 1, food must be given; 2, the fever reduced; 3, the abnormal secretions kept within bounds. The author considers it necessary to feed his patients energetically, but the food must be given in the fluid form. To begin with, a typhoid patient requires a great deal of water, and he should be given something to drink about every quarter of an hour, either milk, or water, or wine and water; aërated waters should, however, be avoided, especially when gurgling is present. Then, as regards nourishment, milk is the chief article to rely upon, but broth mixed with white of egg is a very useful addition. From a quart to a quart and a half of milk a day, together with the whites of three or four eggs, mixed with broth or soup, will enable a patient to get through an attack of typhoid fever, together with a little stimulant each day. It is most important to insist, on those nursing the patient, that a chart should be kept stating the times food is given, also the quantity taken each time, so that at the end of every twenty-four hours, the exact amount of nourishment taken can be calculated. When the fever has subsided two or three days, the patient may have a little calves' brains or sweetbread, with a little cocoa or chocolate; after a week without fever, a little scraped raw meat, about a teaspoonful at a time. The author holds that in every case of typhoid wine is necesary, at first sparingly, but if there be signs of cardiac weakness, then alcohol should be given freely. A bad case of typhoid can take a very large quantity of alcohol daily without any effect being produced upon the mental condition. As far as the second point indicated, viz., combating the fever, it does not shorten an attack to give antipyretic remedies; even though the temperature be kept near normal, the disease runs its course just the same; the judicious use of the bath, either hot or cold, does, however, benefit many cases; in the early stages the cold bath acts best, but after the second week it is better to employ lukewarm baths at a temperature of 86° to 90° F.

Treatment of Whooping-cough by Insufflation—Moizard has used the following:

Benzoin. pulv.,	
Bismuth salicylat. . . .	āā 5 parts.
Quiniæ sulphat.	1 part.

Insufflation through a simple tube (rubber) from three to five times daily.—*Revue Générale de Thérapeutique*, July 14, 1887.

Tracheotomy after Intubation.—Dr. Irwin H. Hance, of New York, has collected (*Medical Record*, June 25, 1887) nine instances of intubation in which tracheotomy became necessary. Recovery followed in five instances, death in three, and the result in the ninth was not reported. This record suggests an important query: Would the recoveries have been fewer had the tracheotomy been performed in the first instance? The showing would be an unusually good one for uncomplicated tracheotomy without the delays of intubation and subsequent accidents, such as slipping of the tube. On the other hand, did the previous intubations render the tracheotomies less dangerous? Who knows?

Vesical Papilloma; Suprapubic Incision; Recovery.—Wiesinger reported the following case to the Medical Society of Hamburg:

Patient, aged sixty-one, had symptoms of vesical papilloma, hæmaturia, pain, pus and débris in the urine. He was treated by suprapubic incision; removal of the mass, which filled the bladder, by the fingers, curette, and Paquelin cautery; tamponing with iodoform gauze to prevent hemorrhage; non-closure of the wound. Tampons remained in the bladder eight days. On the tenth day after operation digital examination revealed a spot of roughness which was removed by a sharp spoon; tampons again inserted for one day. Wound entirely healed six weeks after operation. Patient in good health five months afterward.—*Deutsche medicinische Wochenschrift*, July 7, 1887.

Méthylal.—In *Le Progrès Médical* of July 2, 1887, Mairet and Combemale report forty-one cases of mental disease in which this drug was used as a hypnotic. They conclude as follows:

The drug has little effect in acute alcoholic mania, and in the first stages of ordinary acute mania; in the later stages of mania and in the various dementias it is a useful hypnotic in doses of from 75 minims to 2 drachms; in some forms of dementia the dose may be reduced to 75 minims. For the first five or six days a good effect is produced, which does not continue, and an interval of two or three days must then elapse before the nervous system is again susceptible to its influence. Méthylal they found to be a pure hypnotic, agreeable to take and without ill after-effects.

The Treatment of Sunstroke, in Children, with Antipyrin.—Demme, of the Children's Hospital in Bern, reports the case of a boy three years old, in whom heat prostration caused severe cerebral hyperæmia with eclamptic convulsions, whose temperature was 40° C. After 3 doses of 4½ grains of antipyrin in hourly intervals the temperature fell to 36.7° C., and the convulsions ceased. For three days the temperature varied between 36.4° and 37.8° C. On the morning of the fourth day the temperature rose to 39.3° and an exanthem resembling measles appeared on the trunk, extremities, and lower portion of the face. The exanthem disappeared in three days. After two days another rise of temperature to 39.7°, with convulsions and symptoms of cerebral hyperæmia, occurred; antipyrin, in the doses given before, produced promptly a fall of temperature to 37.3°. On the fourth day afterward another rise of temperature to 38.3° C. and a recurrence of the eruption occurred, although to less extent. The case is interesting from the presence of

the ... with ... of fever.—*Wiener ... Presse*, July 17, 1887.

APPLICATIONS FOR ACNE.—HEBRA'S the following:

Sulphur. præcipitat.	
Potass. bicarbonat.	
Glycerin.	āā ʒss.
Aquæ lauro-cerasi	
Spts. vini	

A favorite lotion at the Hospital of St. Louis, in Paris, is

Sulphur. præcipitat.	½ to 1 part.
Alcohol. camphorat.	1 "
Aquæ rosa	100 parts.
Aquæ destillat.	150 "

Shake before using.

To be applied every evening with a brush; an ointment of zinc oxide may be used during the day.—*Revue Générale de Thérapeutique*, July 14, 1887.

ANÆSTHESIA BY CHLOROFORM AND OXYGEN.—DR. KREUTZMANN, of San Francisco, reports his results with this method of anæsthesia in twenty-five cases, as follows:

Especially noticeable in a number of instances was the rapid action of the mixture of chloroform vapor with oxygen. Thus, it was repeatedly observed that after a few respirations the patients were sufficiently anæsthetized to permit of the performance of an extremely painful operation without occasioning the slightest suffering, as, for example, the introduction of a catheter in cases of violent urethritis and cystitis, brisement forcé, unaccompanied by any irritation. All reflex remained, nor were the patients completely narcotized, but they had no perception of pain whatever. When the administration of the anæsthetic was discontinued, they recovered consciousness almost immediately, were perfectly rational, felt entirely well and remained so. The patients were only in exceptional instances affected by very slight headache and nausea.

In other cases a complete anæsthesia was obtained, with cessation of all reflex action, for the purpose of making larger operations. Here, as well as with the others, the general feeling of ease and freedom from vomiting and retching and absence of headache was a striking circumstance.

Children and younger persons were placed under its influence quickly and easily, whereas chronic drunkards required a longer time, and slight excitation, such as raising the head and attempts to remove the inhaler, were noticed. They were, however, nothing to compare with the frantic struggle made when ether or chloroform is used, nor did any disagreeable symptoms follow.

The anæsthetic used in conjunction with the oxygen was Billroth's mixture, and the amount required to produce its complete effect was astonishingly small.

The discoverer of this method, Dr. Neudorfer, of Vienna, claims, on theoretical grounds, that its employment is entirely without danger.—*Pacific Medical and Surgical Journal*, August, 1887.

AN IMPROVED CAUSTIC PASTE.—DR. JULES FELIX, of Brussels, having found existing caustics unsatisfactory from the great pain which is caused by their application, from the difficulty of limiting their action precisely to the part desired, from their deliquescence and from various other causes, has devised a form of caustic paste which he has been using for some time past with the best results. It does not cause severe pain or set up any general reaction; the eschar is hard and well defined, so as to be easily detached. It is also a powerful antiseptic and hæmostatic. It is not deliquescent, but keeps its consistence, which is that of putty, well, and so lends itself easily to manipulation. The hands should be well wetted when applying it. They are not in any danger of being acted on. The paste is allowed to remain for from six to twenty-four hours according to the amount of eschar which it is desired to form. The formula for the paste is as follows: Mix in a mortar the following substances in powder: Starch, 37 parts; wheat flour, 112 parts; bichloride of mercury, 1 part; dry chloride of zinc, 110 parts; iodol pure, 10 parts; croton chloral, 10 parts; bromide of camphor, 10 parts; crystallized carbolic acid, 10 parts. Then add gradually a sufficient quantity of distilled water to form a homogeneous paste without lumps of the consistence of putty. This paste will keep an indefinite length of time.—*Lancet*, August 6, 1887.

SOLUTIONS FOR VESICAL DOUCHES.—ULTZMANN, of Vienna, has used the following with good results:

For an irritable bladder lukewarm water with a little tincture of opium; solution of cocaine ¼ per cent; resorcin ½ per cent.; carbolic acid ⅙ per cent. When urine decomposes in the bladder solutions of potassium permanganate ⅒ per cent., or 3 drops of amyl nitrite to a pint of water are injected. For phosphaturia ⅓ per cent. salicylic acid is used.—*Centralblatt für Chirurgie*, July 23, 1887.

THE PREVENTION AND TREATMENT OF FLY BITES.—MYLIUS, of Leipzig, has found that flies have a most acute sense of smell, and that the irritation of their bites is caused by an acid lodged in the wound by the sting. After a long series of experiments with ointments and perfumes, he failed to find a satisfactory agent for preventing fly bites, which could be conveniently used with children. As a means of treatment Mylius has prepared pencils of ammonium carbonate, camphor, and menthol which can be instantly applied after a bite. Occasional cases were observed in which the sting had entered the lymphatics producing more severe infection. Such cases may be treated by cold compresses saturated with equal parts of dilute carbolic acid solution and lead water, to which is added 10 per cent. spirits of camphor.—*Deutsche medicinische Wochenschrift*, July 21, 1887.

ANTIPYRINE BY SUBCUTANEOUS INJECTION, IN COMPARISON WITH MORPHINE.—GERMAIN SÉE has employed this drug by injection in doses of a Pravaz's syringe, which contained a solution of eight grains dissolved in an equal weight of water. It first effect was local pain, and a sense of tension, which was followed by its analgæsic effect. It possesses the advantages of morphine, especially in gouty pains and in neuralgia, without its inconvenient after-effects.—*Gazette Hebdomadaire*, July 15, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SATURDAY, SEPTEMBER 3, 1887.

THE INTERNATIONAL MEDICAL CONGRESS.

THE great event in the medical world for the coming week is the meeting of the Ninth International Congress in Washington. The first of these congresses was held in Paris, in 1867; the second in Florence, in 1869; the third in Vienna, in 1873; the fourth in Brussels, in 1875; the fifth in Geneva, in 1877; the sixth in Amsterdam, in 1879; the seventh in London, in 1881: and the eighth in Copenhagen, in 1884. The original intention was that they should be held every second year, but it was thought best to defer the Vienna meeting until the year of the great international exposition; and, at the London meeting, it was decided that once in three years would be as often as it is desirable to have such congresses in the future.

The great object in these meetings is increase of knowledge, individually and collectively, by bringing together from all parts of the world men engaged in all departments of medical science and practice, that each may teach that which he knows better than anyone else; and may learn something, if it be only the breadth and depth of his own ignorance. This is effected, not merely by formal papers, but by the discussions in the Sections, and still more by personal intercourse.

The papers and addresses will be printed, the discussions will be reported, and one may consider these at his leisure; but the informal conversations with, and the glance of the eye and the facial expression of, the men whom we recognize as leaders in investigation, in thought, and in practice, cannot be reproduced.

Such meetings exercise a powerful stimulus upon all who know how to accept their benefits. There are a few men always in the world who not only do good work themselves, but who arouse in all who meet with them a desire also to do good work. No one can meet and listen to such men as held the most prominent positions in the London and Copenhagen Congresses, the recognized leaders in European medicine, without feeling that he is in the presence of those who are working to advance medical knowledge with little thought of pecuniary reward, of personal ambition, or of desire for applause; and this feeling will make him an humbler and a better man, and, so far, a wiser one. It is not the business of such Congresses to legislate, or to express opinions on local matters. As Professor Panum, the President of the Copenhagen Congress, said in his opening address, "Nationality does not count in science, it should have nothing to do with our Congress. We are not here to discuss national or political problems, on the contrary, all discussion upon such subjects ought certainly to be forbidden here."

At all events, the less conspicuous medical politics and medical politicians are in these international gatherings the better it will be for their reputation and permanent influence for good.

We hope that the Washington Congress will steer clear of all pitfalls, make important contributions to medical science, and leave behind it nothing but pleasant memories in the minds of all who attend it. The prospect is that the meeting will be a large one, and that there will be a superabundance of papers to hear and discuss, while the element of social enjoyment will not be deficient. If the weather is favorable, as there is every reason to believe that it will be, those who visit Washington next week may be sure of having a good time, and we offer our best wishes that the Congress may be as complete a success as those who have charge of its organization desire to make it.

THE MEDICAL NEWS will have a large staff of special reporters and correspondents in attendance at the Congress, and complete arrangements have been made for promptly placing before our readers a full report of the proceedings.

THE ANTAGONISM BETWEEN BELLADONNA AND OPIUM.

THE importance of arriving at an absolutely correct opinion as regards the antidotal influence of atropia in opium poisoning cannot be over-estimated, since, of all forms of toxæmia due to vegetable poisons this is the most commonly met with, not only by the hospital physician, but also the ordinary practitioner. Perhaps no better example of the value of results obtained by experimentation on the lower animals can be adduced than the benefits derived from our increased knowledge of the physi-

ological action of the two drugs whose names are at the head of this article.

Those of our readers who thirty years ago listened as students to lectures on therapeutics and kindred subjects, will remember that although the symptoms and treatment of poisoning by opium were dwelt upon as important matters, that very little was known as to the direct causes of the signs or the reason for the treatment. Now we know that opium kills by depressing the respiratory centre, and that atropia acts as an antidote by stimulating it, and we also have such additional knowledge as will enable us to treat such cases understandingly, and with real reason.

Notwithstanding the fact that almost all writers believe atropia to be our mainstay in such cases, it is but right that evidence to the contrary should be at least brought to general notice; and in quite an exhaustive paper by LENHARTZ, in the *Deutsches Archiv f. klin. Med.*, 40 B., 5 and 6 Hefte, the whole question now before us is most thoroughly aired from an almost purely clinical standpoint, by means of reports of cases and the aid of a considerable amount of bibliographical labor. The article as a whole, while not denying the usefulness of atropia as an antidote in opium-poisoning, rather decries its constant use, and points out that certain serious symptoms may arise if atropia be used. To be more concise, Lenhartz believes that the unqualified approval of atropia as an antidote in opium-poisoning, so commonly found in the text-books, should be regarded with disfavor, and that the drug should only be used as one of many remedies, and given with a full understanding of the conditions present.

We cannot help feeling that Lenhartz is right in this matter, and the importance of withholding atropine at certain stages of the poisoning can best be recognized by the recollection of the physiological action of the two drugs. It will be remembered that in opium poisoning we have three stages, in the first there may be slight feelings of drowsiness ending with sleep, in the second a constantly deepening sleep with a slow, full, strong pulse, and respirations constantly decreasing in frequency, while in the third stage there exist a rapid, running, feeble pulse and profound depression of respiratory movement. This rapid, feeble pulse in the third stage is simply due to palsy of the peripheral vagi and depression of the heart muscle and its ganglia, coupled with the exhaustion resulting from ventricular distention due to the impaired pulmonic movements. If the reader now calls to mind the fact that atropine is likewise depressant to the heart muscle even in medicinal doses, it at once becomes evident that the use of atropine in this last stage of opium poisoning may, while stimulating respiration, so depress the heart as to bring on serious circulatory symptoms or perhaps death.

While we may rely on atropia in the first and second stage of the poisoning, in the third stage we think it may be laid down as an invariable rule never to use atropia unless accompanied by cardiac stimulants, and that even then the patient should be most carefully watched for signs of circulatory disturbance. It is very evident from the history of most of the cases in which unfavorable results have been reached under the use of atropia that the condition of the circulation was overlooked by the attendant when the drug was administered, and that death resulted from cardiac failure in the manner just stated.

THE MT. HOLLY EPIDEMIC OF TYPHOID.

THE direct causation of typhoid fever by water containing the bacilli peculiar to this disease has again received a positive demonstration in the recent epidemic at Mt. Holly. The attention of the profession has been drawn of late to this subject by the typhoid epidemic at Plymouth, by the cases at Pierrefonds, by the Conanicut Park Hotel cases, and by the recent biological examination, by Dr. Ernst, at the Harvard Laboratory, of the water furnished the steerage passengers on an Atlantic steamer, the use of which was followed by a typhoid epidemic.

It would seem as if no frequent cause of disease had been so thoroughly proven as contaminated water in the production of typhoid fever, and yet the duty which this established relation of cause and effect imposes is frequently neglected by those responsible for the sanitation of a community or a household. While health legislation may be attended by the delays usual in politics, yet thorough scrutiny of the sources of water supplies is as imperative upon the physicians and citizens of a town as are the performance and regulation of vacinnation; and the public will not heed properly this obligation until sanitary administration shall be made equally stringent upon this point.

The most remarkable result of the scientific study of the Mt. Holly cases, by DR. LEEDS, in the present issue of THE NEWS, is the demonstration of the fact that a quantity of alum, so small as not to injure water for drinking purposes, is sufficient, not only to clarify it, but also to reduce greatly its bacterial contents. If further investigation establishes the value of alum as a germicide, we shall be in possession of a readily available agent well calculated for use in these cases.

Dr. Leeds' investigation is of great value and interest, and the further trial of alum in the capacity indicated will be an important and useful experiment.

RAILWAY BRAIN.

At a recent meeting of the Society of Physicians of the Charité Hospital, in Berlin, Thomsen exhibited a patient whose case he described as one of "railway brain," a neurosis resembling in many respects the condition already well known under the name of "railway spine." A healthy railway employé, aged thirty, without history of alcoholism, or of any predisposing neurotic condition, by the sudden motion of his train was thrown violently against the side of a car, striking his head. He sustained no wound, and at the time of injury consciousness was preserved. Some hours afterward, however, he was suddenly seized with syncope, with mental terror, lost all sense of location, could not recognize the simplest familiar object, and described what he saw erroneously; his one objective symptom was absolute anæsthesia of the entire body. On the fourth day after his injury he had violent headaches, a pulse-rate of 44, and, in addition to the cutaneous anæsthesia, loss of olfactory and taste sensations, with difficult hearing. On the fifth day the psychic symptoms suddenly ceased, he could remember nothing which had happened, and had no explanation for his condition.

The patient subsequently became very melancholic, complaining of insomnia, headaches, spinal pain, weariness, and failure of appetite; no sensations of terror or disordered dreams were present. The objective symptoms remaining were well marked cranial and spinal hyperæsthesia; failure to distinguish between white and colors; loss of smell and taste, and impaired hearing; numbness, and at times paresis and spasms, of the region supplied by the facial nerve were also present. He was discharged from the hospital as improved, but two months afterward his condition was unchanged; he was unable to work on account of headache and weakness. Thomsen's diagnosis was "railway brain," a condition of profound disturbance of cerebral functions from shock. The prognosis he stated to be doubtful; the treatment hygienic and palliative.

The increase in mechanical appliances, and the immense extension of railways, afford abundant opportunities for observation of nervous shock, both in its fatal and milder forms. While post-mortem demonstration of hemorrhage and structural lesions explains the course of these cases when fatal, it is evident that we must rely upon the continued observation of surviving patients to determine the development of lesions which will illustrate the pathology of this condition. The possibility of the production of degenerative changes in nervous matter, and cerebral conditions causing permanent mental impairment, is an interesting question for neurologists, and, in its medico-legal aspects, for the corporation whose property may cause such injuries to their patrons and employés.

STENOCARPINE.

The recent discovery of a new anæsthetic substance in the leaves of a tree abundant in Louisiana, and the experiments made with this substance by Dr. Jackson, of Philadelphia, whose paper appears in the present issue of The News, as well as the observations of Drs. Claiborne and Knapp, of New York, are of the greatest interest.

The properties of cocaine have become so well known that it is but natural that the anæsthetic effect of leaves, gathered by chance, and expected to serve only as retainers of heat and moisture, should have aroused curiosity in an intelligent mind. The demonstration of the presence of an alkaloid possessing anæsthetic powers superior to cocaine, and also mydriatic effects exceeding those of homatropine, renders this substance highly valuable in therapeutics.

The Australian alkaloid, drumine, the most recent rival to cocaine, has not realized the expectations of its discoverers, and if American forests can furnish a substance combining and exceeding the actions of two of the most valuable alkaloids now known, it will demonstrate anew the medicinal value of the flora of America, and should stimulate a more complete study of its resources.

The record of yellow fever cases at Key West up to August 28th, according to the reports of the Board of Health, is as follows: new cases, 1; deaths, 60; discharged cured, 171; still sick, 139.

REVIEWS.

Autobiography of Samuel D. Gross, M.D., D.C.L. Oxon., LL.D. Cantab., etc., with Sketches of his Contemporaries. Edited by his Sons. In two volumes, 8vo., pp. xxxii., 407, 438. Philadelphia: George Barrie, 1887.

It is only a few years since the biographical sketches by Drs. Flint, DaCosta, and Hays made the public familiar with the leading events in the life of Dr. Gross. The remembrance in which he is held by the medical profession is as vivid as it is widespread. If it be lacking in the former quality, the present work will do much to fill out the picture and insure its permanence. In the chapter in which Dr. Gross makes an estimate of himself as an author, he refers to the general opinion that he is fond of writing, and proceeds to confess the soft impeachment. Although noted as a man of action in the amphitheatre, many of his happiest hours have been spent in his study, with his much-loved pen for a companion. He evidently found composition an easy task. We like to do what we do well. Fortunately for us he had time in his later years to write the present account of himself and some of his contemporaries.

To make such a story interesting to any but the small circle of intimate friends, it must speak of a man among men who stood in the front of life, and took part in events of importance. While the author's life had no political significance, it had enough in it of the unusual and picturesque to make a pleasing book. One who did so much to give American surgery a name abroad, and who won a deserved eminence at home, must in the evening of his days have memories and reflections well worth attention. He was brought in contact with, and presents reminiscences of men who were first in their callings, including, among statesmen, Jackson, Clay, and Webster; among the clergy, bishops and archbishops, and *savants* of all the sciences upon both continents. Having served in four renowned medical colleges in as many different States, he has much to contribute to the history of these institutions. But his most valid claim as an acceptable autobiographer rests upon the fact that his own life had in it the element of interest due to exceptional incidents and situations. When to this element we add a sense of humor and wholesome good nature in the writer, who has the art of keeping his alert individuality constantly before us, we have a story which is sure to be read with satisfaction, and prove a recreation to the reader. His style is simple and clear, but as the man was positive so his writing is often spirited and pungent. He was a born doctor of the teaching type. His early education was incomplete, though he did much in private study to repair its deficiencies. What he lacked in knowledge of the classics was made up by his acquirements in French and German. These were, for the medical career, of more importance, and there is proof that they were of material help to him all through life. He had an energy which prompted him to be an investigator and a producer of books and essays upon many different subjects. He had a decided talent for public speaking. To a fine presence and great fluency of speech he joined a mellow, well modulated voice, graceful action, and an enthusiastic delivery. These were sure to captivate his audience in the beginning. His popularity as a teacher was due further to the art with which he economized the students' power of attention. Having informed himself thoroughly on his subject, he took a plane of thought just above his auditors, but in the line of easy vision. They were thus enabled to see the truths he would inculcate without changing their natural intellectual posture. It was never an effort to follow him, and without the least straining his students took hold on the principles he presented.

In the larger part of the present book his constant theme is, as it ought to be, himself. Yet he writes of himself with studious moderation, and keeps within the bounds of perfect taste. Under the headings of "Professional Income and Fees," "Teaching," "As a "Practitioner," "As a Writer and Author," "Habits," "Labors," he attempts to estimate impartially not only his character but his achievements. And though he makes a statement which, to say the least, is free from exaggeration, the general effect is inspiring to those who, with a small opinion of their own merits, would yet do something with their lives better than common. As a specimen of a great deal that is wholesome for the reader, we may take this paragraph: "The position which I have attained in my profession has been achieved by hard blows, by no special intellectual endowment, by no special gifts from God, by no special favor from man, but by my own unaided efforts, continued steadily and perseveringly through a long series of years, during which a kind Providence afforded me sound health, lofty ambition, and unflinching fidelity to my profession." Occasional pages of literary power are encountered. Such, for example, is the picture drawn of the hardships of the surgeon. As an offset to sentimental objections to cremation, the cremation society might make use of this passage: "I want to be useful when I am dead, which I cannot be if I am stuck away six feet into the earth. If I am burned, my body will enter again into new creations, and thus be subservient to some useful purpose. It may assist in animating a flower, in ornamenting the plumage of a bird, or in directing the movements of a caterpillar."

Several chapters are given to an account of his European travels. What is personal to himself and the distinguished men who delighted to do him honor, will be read with interest, but we must frankly express the opinion that this narrative of travel is not equal to the best part of his work. One-third of the second volume may be deemed supplementary, as it is devoted to "sketches of some distinguished contemporaries." Most of these were medical men of note, with whom the writer had some connection as colleague. Taken together, these sketches serve not only to portray individuals, but by small touches outline the times in which they figured. Some of them demonstrate that friendly partiality which was always a winning trait of Dr. Gross. He was a very appreciative friend, but even his rivals and opponents are handled humanely in these highly readable pages.

The editors, Dr. S. W. Gross and A. Haller Gross, Esq., deserve a word of commendation. With so many proper names to deal with, the errors are surprisingly few.

They did well to include the memoir by Dr. Flint, which gives information needed to make the history complete, and is itself a testimony so well rounded as to leave little to be desired. The epitaph by Dr. Yandell, which is fitted to it by the editors, makes an admirable finish. The index is copious, and together with the engraved frontispieces, the heavy paper, and perfect type work, gives to this worthy book a satisfactory, indeed, an elegant form.

CORRESPONDENCE.

PROFESSOR VON BERGMANN'S CLINIC.

Among the distinguished surgeons of Germany, Prof. E. von Bergmann, stands in the first rank. His many contributions to the science of surgery, his wonderful skill in the art, and his brilliant results justly entitle him to the position of President of the Congress of German Surgeons, to which he was elected at the last meeting. His daily public clinics, which are well attended, are very interesting and instructive. The richness of the material of his hospital, the *Königliches Klinikum* is such, that only a selected portion of the operations are made before the class. He is even able so to arrange as to have several cases for similar operations at the same clinic, or various morbid conditions of the part to point out the differential diagnosis.

It was with great pleasure and profit that I attended these clinics during the summer semester, which has just come to an end, and it may not be without interest to the readers of your journal to give a short account of the work done.

The wonderful results of thorough and intelligent antiseptic precautions are nowhere better shown than here. When it is seen that major amputations are brought before the class on the twentieth day completely healed, that cases, in which extirpation of the rectum with opening of the peritoneal cavity has been made, go on to recovery without any fever, that in a case of partial excision of the superior maxillary bone with removal of all the walls of one orbit, opening the membranes of the brain, and its prolapse, the patient recovers without an untoward symptom, when, in fact, the prognosis of an operation, where there was no previous sepsis, can be made with almost as great certainty as that of a simple fracture, it cannot be but useful to look into the special methods under which this is accomplished.

The antiseptic precautions are vigorous though simple. Besides a preliminary bath, the surfaces in the wide neighborhood of the scene of operation are shaved, and immediately before operating again thoroughly washed with soap and water and brush, and then with a strong solution of corrosive sublimate ($\frac{1}{10}$th per cent.). All those parts adjoining the field of operation are then wrapped in or covered by towels wrung out in the sublimate solution, and with this same solution the wound is frequently irrigated during the operation; no spray is used. The instruments are kept in a solution of carbolic acid during the operation; they have for the most part smooth metallic handles, which are easily kept aseptic. Sponges are seldom used, little bats of soft, sterilized, crinoline gauze taking their places, though the former are sometimes indispensable in very bloody operations. All those engaged in the operation are dressed in clean, white gowns—and the most careful washing and disinfection of hands is observed before every operation. Comparatively little blood is lost, for two skilled assistants are constantly ready with artery forceps to grasp every bleeding spot, however small it may be. This thorough control of subsequent hemorrhage is certainly one of the factors of success.

The disinfection of a wound after an operation is accomplished by means of the sublimate solution or of *iodoform-ether*. The latter, a simple 10 per cent. solution of iodoform in ether, is a favorite disinfectant after operation on bone, after exsections of tuberculous joints, and whenever a tampon will subsequently be left in the wounds. This solution possesses all the virtues of powdered iodoform, beside the additional advantage that it thoroughly covers the whole surface in all its recesses, and after all excess of the fluid is removed, but a very small quantity of iodoform is left in the wound. Furthermore, the charge of bringing microörganisms into a wound cannot be made against this agent, as it has been against the powdered form of iodoform. Wounds, it matters not how large, if their surface can be brought together, are closed immediately after the operation, sutured and covered with a permanent dressing, drainage tubes being often used, especially in the larger wounds.

The very largest wounds only, such as amputations of the thigh, are reëxamined on the third day. After operations on bone or in joints, an iodoform-gauze tampon is left in the wound for about two days, and at the end of that time removed, and the wound then is closed by sutures, a proceeding which, he shows, does not interfere with union by first intention. In those cases also where there was previously a septic condition, for example, an amputation for gangrene, he does not close the wound immediately, but treats similarly, closing it on the third day, if everything goes well. On the other hand, he strongly disapproves of the practice of tamponing an abscess cavity, which proceeding, he claims, results in the collection of pus in the wound—here he uses drainage tubes and plenty of them. His dressings consist of sterilized crinoline-gauze, containing corrosive sublimate and absorbent cotton. Bandages are also made of the former material. A few layers of iodoform-gauze are also frequently used, being applied directly over a wound. These dressings are always applied dry, and allow rapid evaporation to go on through them, a property upon which Prof. v. Bergmann lays great stress, for, as shown by Esmarck, they allow the deepest layers to remain dry, and dryness is most unfavorable to the activity of microörganisms.

To make a short sketch of the work done during the last three months, the duration of the summer semester, I cannot do better than repeat the *résumé* given by Professor v. Bergmann at the end of the last clinic. Excluding the opening of abscesses and the like, there were 124 greater operations. Of these, there were to major amputations, beside 2 at the hip-joint. There were 18 resections of larger joints, 12 of which were at the knee, 4 at the hip, 1 at the shoulder, and 1 at the elbow. There were 8 osteotomies (made for different conditions, *i. e.*, genu valgum, rachitic curvature of the legs, etc.), 5 necrotomies (in two of these the bones were chiselled out for osteomyelitis spontana acuta), 3 operations for pseudarthroses, 3 incisions or punctures of joints, with irrigation with a solution of carbolic acid, one case of removal of depressed bone in a compound cranial fracture. The number of morbid growths removed was 47, of which 16 were benign. There were 5 carcinomas of the breast, 2 of the rectum; 10 malignant tumors of the face, neck, occiput, axilla, and femur (1 fibroma, 1 adenoma, 3 cysts); 3 of the testicle; 2 congenital cysts; 3 goitres; 3 lipomas of the back of the neck; 1 hydronephrosis; 2 housemaid's knees; 3 simple sebaceous cysts; 1 gouty knot from the plantar surface of the foot; 4 lymph cavernomas, and also the removal of a large number of tuberculous lymphatic glands of the neck in five cases (in which the internal jugular vein was frequently laid bare in almost its whole course, or even partly excised. Beside these there were 2 cheiloplastic operations, 1 rhinoplastic, 1 operation for artificial anus, 5 lithotomies (4 sectio altoe, and 1 sectio mediana); 3 for hemorrhoids (clamping and burning them off); 2 external urethrotomies; 1 myotomy (for torticollis); 5 radical operations for hydrocele; 3 castrations; 2 herniotomies, and 2 tracheotomies. Besides, a great number of patients were demonstrated, who had been operated upon at other times, or who presented interesting surgical affections, but who were not operated upon.

There are a few of the operations above, which deserve special mention. The rhinoplastic operation was made in imitation of the new method of König, accord-

ing to which a rectangular flap, consisting of skin, periosteum and the outer lamina of the frontal bone, having a broad pedicle at the glabella, serves as a bony support of the nose. Its osseous surface is turned out, and is subsequently covered by skin, after the flap has become properly adherent. The hip-joint amputations consisted in a preliminary subtrochanteric circular amputation, made while the leg was constricted by a rubber tube applied as high as possible, and, after all the vessels had been tied and the tube removed, the subsequent excision of the head and remaining portion of the femur through a longitudinal incision over the greater trochanter. As no large vessels are cut in the latter incision, the whole operation can be made with little loss of blood.

The radical operation for hydrocele advised by Prof. v. Bergmann and performed in all the cases above mentioned, requires a long scrotal incision, and the peeling out and removal of the parietal portion of the tunica vaginalis. All bleeding vessels are tied, and the wound sewed, leaving a small drainage tube in the wound for two days, if there is any tendency to subsequent bleeding. It heals by first intention in eight or ten days, or if a drainage tube was used, in a few days more. The advantages which he claims for this operation are that it is the most radical cure, and that it allows all portions of the sac to come into view, so that other morbid conditions, sometimes the real causes of the hydrocele, are not overlooked. HARRY FRIEDENWALD.

BERLIN, August 1, 1887.

REMOVAL OF THE UTERUS THROUGH THE VAGINA.

VAGINAL hysterectomy has passed through phases in its history like those of ovariotomy, and of many other capital operations. Beginning with a crude technique, and a very large percentage rate of deaths, and in the hands of but a few bold operators, it has now at length reached a status which bids fair before long to secure for it a recognition in the list of *safe* operations.

The first great step toward progress has been made in the establishment of the fundamental principle that no case is suitable for this operation in which the cellular tissues in the neighborhood of the uterus have been invaded; this fact being determined by the mobility of the organ, or the detection of infiltration or nodules by careful palpation, rectal, vaginal, vesical, or abdominal. Again, one after another of the serious difficulties in the technique have been met, and correct procedures established, so that it would finally seem that in the hands of some, but little was left to be desired.

While, however, this has been the natural history of the operation throughout Germany, in England and America the results have been the same. Cancerous disease of the uterus is in the latter rarer, and operations more than proportionally fewer, and the mortality of total exturpation great, in inverse proportion. The propriety of performing the operation *at all*, is still open for discussion; and, as a rule, palliative scrapings and applications have the preference.

It is scarcely more than a year since one of the most distinguished ovariotomists of England said to me, upon my informing him that my purpose in visiting Germany was mainly to study vaginal hysterectomy, "that is an operation which I hope you will never do." I will not here open up the question of propriety for any general discussion, hoping that the specific matter which I am about to offer will speak for itself in no uncertain tones.

Given a disgusting foul disease, extremely painful, lingering, and with absolute certainty progressive toward death, what living woman would not accept an operation tending toward a radical cure, with a death rate *less than seven per cent.*, and with a percentage rate of 69.2 per cent. of cases absolutely free from any signs of relapse after one, two, and three years? Such is the record I have the pleasure of offering at the personal request of Prof. Leopold, of the Obstetrical Institute at Dresden. He especially wishes that his work, an account of which has been published in the *Archiv f. Gyn.*, No. xxx. Heft. 3, should be appreciated by American surgeons, hoping that it will in some measure influence their practice.

The results in general have been that, *out of forty-eight cases* upon which he had operated, removing the entire uterus per vaginam, but *three died*, or 6.2 per cent. I make also the following deductions from a carefully arranged table included in the work referred to.

Out of 48 cases, 42 were cancerous, and out of these 42 but 4 involved primarily the body of the uterus, 38 being cancer of the cervix, preponderatingly "mush-room form." Most of which latter we, in America, will readily attribute to lacerations of the cervix, with eversion, infiltration, cystic formations, and, if not constant and consequent, the very frequent *concomitant*, later epithelial activity and cancerous formation. The youngest cancerous patient on the list was thirty-three years old, three being under thirty-five, and two over sixty.

The method by which these remarkable results were obtained is briefly the following: By steady traction upon the cervix uteri, slowly and step by step the appendages are brought down and tied off in small bundles. Torsion of the uterus on its transverse axis is avoided, and the utmost possible care taken to prevent loss of blood, including the assurance of freedom from any danger of secondary hemorrhage. After a thorough preparation of the patient by baths, local douches, attention to the condition of the bowels, and fluid but strong food before the operation, she is put upon the table in the dorsal position, and the vagina carefully washed out with a five per cent. solution of carbolic acid. All carcinomatous material is scraped and washed away under an irrigation of the five per cent. solution.

The uterine cavity is also most carefully cleansed with the same solution applied on cotton. The cervix is then caught and held firmly by Museux or other strong forceps, and a semilunar incision made around its anterior two-thirds, close below but avoiding the limits of the base of the bladder, generally indicated by a fold, and as far as possible from the limit of cancerous tissue. The index finger is then at once forced through the incision, separating the vaginal vault right, left, and in front, as far as possible, keeping the finger close to the cervix. The bleeding, mostly from the cut vagina, is checked by four or five ligatures passed through the vault, close to the margin of the incision. Extreme care may sometimes be called for by the degenerated condition of the tissue between the uterus and bladder, and it may be necessary here to pull down small portions and tie them off, with the utmost respect for the position

of the bladder-wall, as indicated by a catheter. Thus the first step is completed.

The second consists in connecting the angles of this anterior incision by an incision posteriorly, in which the bleeding is also controlled by ligatures embracing the vaginal mucous membrane, at the outer margin of the wound. These ligatures through the vaginal vault *are all left long*. With the index finger the tissue posteriorly is also pushed up, and the cervix freed; then by catching up the loose cellular tissue just behind the cervix posteriorly, with a pair of forceps, the knife readily opens Douglas's pouch with a cross cut, into which a sponge about the size of a walnut is pressed, fastened to wire, wrung out of a five per cent. solution of carbolic acid. The bleeding, which is very apt to be continuous after this incision, is checked by sutures from the vaginal surface, near the cut, up into the angles of the peritoneum on either side, in a loop, and out again on the vaginal surface and tied. The steps in the operation thus far have succeeded in checking all hemorrhage, by the series of loop ligatures in the vaginal vault near the margin of the incision. The bladder has been pushed up, the cervix freed, and Douglas's pouch opened.

It now remains to tie off the broad ligaments on each side, and to free the bladder at its peritoneal reflection, and the hysterectomy will be completed. To separate the left broad ligament, the cervix is drawn strongly to the right with forceps, the index finger slipped in *behind* the left ligament, and the nearest presenting portion hooked down on the crooked end of the finger. On this finger as a guide, the dull needle threaded with stout silk is carried in behind, and the presenting tissue transfixed, the silk secured, and the needle withdrawn. The ligature is tied very securely, *left long*, and the tissue between it and the uterus carefully snipped with scissors.

This step is repeated many times, each time reaching a step higher up, until the tube is reached, but not yet tied. In the same manner, *mutatis mutandis*, the right broad ligament is separated from its uterine connection including tube. The vesico-uterine fold is now readily tied, and the *uterus* thus freed and *removed*.

Tubes and ovaries are only removed when they present readily in the field of operation.

Finally, the utmost care, and as much time as necessary, are employed in seeking out all possible sources of hemorrhage, which must with certainty be checked. Scarcely any blood has been lost throughout the whole of this operation, and the ligature of the parts *en masse* has been carefully avoided, and with the after-attention the results have been such that in the whole forty-eight cases but one secondary hemorrhage has arisen.

After removal of the sponge, and further careful cleansing with similarly prepared sponges if necessary, the ligatures are gently drawn down, and iodoform dusted lightly into the now funnel-shaped wound, a small roll of iodoform gauze laid in, and the same laid in the vagina. The ligatures are cut off at a length of four inches, and the whole vagina further filled with the gauze.

The operation lasts from one to two hours, and the appearance of the patient afterward is that of a woman who has gone through a healthy labor. Patients usually pass water unaided, and the bowels are opened on the seventh day. From the eighth to the tenth day the first vaginal examination is made, and the gauze and some of the loose ligatures removed. From the sixteenth to the eighteenth day the patient rises for the first time, and is dismissed only after she has fairly recovered strength.

Such is the simplicity attained in the technique of an operation which at one time ranked first in its death-rate. My effort has been not to give here that elaborate and minute description of which the operation is so well worthy, but to speak sufficiently in detail to demonstrate its extreme practicability, and, above all, to call the attention of American physicians as well as surgeons to the wonderful results thus attainable.

With the physician lies the serious duty of examining, at the earliest possible date, every woman complaining of symptoms in any possible manner connected with cancer, and it will then be the duty of the surgeon to give the patient the full benefit of such work as that which Professor Leopold has brought before us.

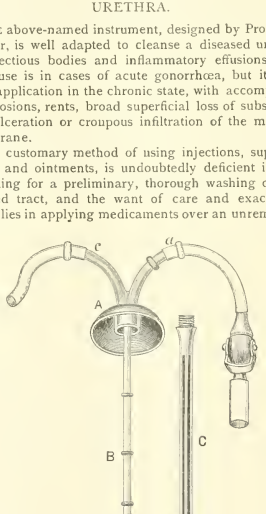
HOWARD A. KELLY.

PRAGUE, July 25, 1887.

ZUELZER'S KATHARAPHOR FOR THE URETHRA.

THE above-named instrument, designed by Professor Zuelzer, is well adapted to cleanse a diseased urethra of infectious bodies and inflammatory effusions. Its chief use is in cases of acute gonorrhœa, but it also finds application in the chronic state, with accompanying erosions, rents, broad superficial loss of substance and ulceration or croupous infiltration of the mucous membrane.

The customary method of using injections, suppositories, and ointments, is undoubtedly deficient in not providing for a preliminary, thorough washing of the affected tract, and the want of care and exactness, which lies in applying medicaments over an unremoved



layer of inflammatory products, needs hardly to be mentioned as incompatible with our ideas of antiseptic treatment.

By the use of the katharaphor this indication is fulfilled, and the ingenious and complete manner of its construction has lead to the belief that it is deserving of notice in America. The accompanying illustrations may serve to explain the instrument:

The bell A is of a size to cover the glans penis. The bent tube *a*, distinguished from its fellow *c* by an elevated ring, is connected with an irrigator of water or antiseptic solution, and terminates in the straight tube B. The latter has a length of $4\frac{1}{2}$–$5\frac{1}{2}$ inches, and ends with a free opening. The outer tube C, encasing B, is screwed into the under surface of the bell and communicates thereby with the outflow-tube *c*. The outer tube is of silver or German silver, its lower end is closed and has a tip like a catheter's. Its sides are perforated by four long, broad slits. The three elevations on B prevent the outer tube C from bending inward.

The current of fluid in *a* B escapes at the open extremity. Through the slits in C it bathes the urethral walls, and the collected washings returning inward again are discharged through *c*. In the treatment of acute gonorrhœa in Zuelzer's clinic, the patient's urethra is irrigated once daily. The liquid is either hot or cold, the latter state being generally preferred on account of the comfortable sensations it produces. The washings are collected in glass vessels until the fluid no longer shows turbidity. By compressing the rubber tube attached to *c* the outflow is arrested. This is done at short intervals and tends to remove particles that would not otherwise come away.

An irrigation lasts from fifteen to forty minutes. It may, of course, when possible, be frequently repeated. Prof. Zuelzer usually combines the use of medicated suppositories, but not with any decided influence on the duration of the purulent discharge. This, as a rule, entirely disappears in from six to eight days, even when pure water is the irrigant.

LOUIS KOLIPINSKI, M.D.

BERLIN, August 6, 1887

NEW INVENTIONS.

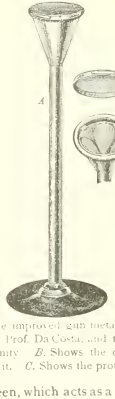
A NEW STETHOSCOPE ON THE AUTOPHONIC PRINCIPLE.

BY R. LEAMAN, M.D.,

DEMONSTRATOR OF CLINICAL MEDICINE IN THE JEFFERSON MEDICAL COLLEGE.

LAST winter Prof. Da Costa, in a lecture introductory to diseases of the chest, suggested that a simple resonating apparatus might be applied to the single stethoscope as others had attempted to apply a microphonic arrangement to the double instrument. This suggestion I laid before Mr. Hentschke, an instrument maker, who has succeeded in making an improvement in both the single and double instrument, which, after due and unbiassed trial, we consider the best instruments in the market. The idea of applying membranes to stethoscopes for the purpose of reinforcing the sound-waves, is, of course, by no means a new one.

Two features, however, are brought out in this "autophonic stethoscope" which are new. The fish skin membrane used can be safely stretched very tight, and is not affected by damp weather; also, the membrane is arranged in such a manner as to form what we might call an autophone. A conical shaped diaphragm is inserted in the conical end of the stethoscope with an



A. Represents the improved gum metal stethoscope, with ear-piece *a*, devised by Prof. Da Costa, and the protecting cap upon the opposite extremity. *B*. Shows the diaphragm with the fish skin stretched over it. *C*. Shows the protecting cap.

interspace between, which acts as a resonating chamber. The result of this arrangement is not only to increase somewhat the loudness of sounds, but it also enables us to define sound better.

In one instance, a heart murmur which was inaudible with the ordinary double stethoscope, was plainly brought out when the resonating chamber was attached. Prof. Da Costa states that with the single autophonic stethoscope he has noticed that the sounds are made clear without the removal of the protecting cap.

Dr. J. C. Wilson informs me that he has "used the autophonic stethoscope with great satisfaction during his past term of service in the wards of the Philadelphia Hospital."

NEWS ITEMS.

CLINICS AT THE INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.—This hospital, which has been well known for many years, has been handsomely rebuilt on the old site, at the corner of Seventeenth and Summer Streets, Philadelphia, and is devoted exclusively to nervous diseases and orthopædics.

The service for outpatients at the hospital has a quite peculiar interest from the mode in which it is managed. In the first place, these clinics are held by the physicians with the assistance of a large staff of assistants. Three rooms on the ground floor, well aired and lighted; a large adjoining room for electrical treatment; a dark closet for ophthalmoscopic purposes; and a photographic chamber, give ample facilities.

The three physicians each hold a weekly clinic, and lectures are now being given twice a week in the lecture room of the hospital.

The method followed at these clinics may be illustrated by a brief mention of the plan adopted by the

senior physician, Dr. S. Weir Mitchell. One of his assistants, Dr. Hinsdale, obtains in one of the case-books the introductory knowledge needed in every instance, and endeavors to form a rough diagnosis; this sketch comes before Dr. Mitchell, who questions the patient and endeavors, as do all the physicians, to follow a printed card which gives the order in which the symptoms shall be noted. This regularity of sequence makes the notes taken more easily comparable. If the notes need to be elaborate, Dr. Morris Lewis examines thoroughly the heart, the lungs, and abdomen; Dr. de Schweinitz the eye and ear; Dr. J. M. Taylor the secretions; while Dr. Massey makes the electrical tests. Each aid has thin slips of paper on which are printed clearly the main points of inquiry, and these, when filled out, come back to the clinical clerk for insertion with the notes of the case. It is rare that all the slips are needed; often a mere negation records absence of heart and lung troubles; but, by this plan, when very accurate notes are needed, they can be had.

Often no opinion is given until a case has been examined at a second visit and a more extended history obtained. It would be difficult to secure more care in diagnosis than is thus attained.

The seven sets of books used in these clinics for records are peculiar to the hospital; they are for epilepsy, chorea, neuralgias, local paralysis and local disease of nerve trunks, paralysis of adults, infantile paralysis, and miscellaneous cases. The plan provides volumes available for examination or inquiry regarding these disorders, and saves the inconvenience of sifting out from a miscellaneous collection the special cases that may be required.

The pages of the chorea book are printed with about fifty questions regarding family history, the previous health of the patient and particularly previous attacks of the disease, the exact date of onset of the present attack, the order in which the members were affected, and very many questions regarding the present condition of the patient. The answers to these questions have secured full statements and have aided the researches on *Chorea and Weather*, by Dr. Mitchell, and on *Chorea and Rheumatism*, by Dr. Morris Lewis, as well as Dr. Mitchell's papers on *Chorea in the Black* and on *Habit Chorea*. At present Prof. Osler is using them to call back to the hospital for reëxamination of the heart all the old cases of chorea, which now number five hundred at least. Dr. de Schweinitz is carefully restudying the eyes of the choreic.

For palsy of infancy case books have been printed with spaces for answers to fifty-eight different items. From a vast collection of cases thus studied Dr. Sinkler was enabled to draw his conclusions as to the relation of the paralyses of childhood to temperature.

The less interesting cases which return frequently, are seen by an assistant, and thus these large clinics are handled with a speed, and yet with an amount of care, which is remarkable.

Medicines are given at a little above cost—at such a rate, in fact, as merely to pay for the drugs and sustain the apothecary.

These clinics are, as a rule, open to all visiting physicians; but we believe Dr. Mitchell, at least, declines to lecture clinically to a mixed class of men and women, and thinks that opportunity for study is lost by teaching at clinics of this kind.

The electrical service under Dr. Massey is very complete, abundant facilities being provided for the use of galvanic, faradic, and franklinic currents in the electrical room and throughout the house. By a novel arrangement the galvanic current is made available for use at the bedside of each patient in the hospital, and all may be treated simultaneously without danger of exhausting the battery. This is accomplished by using the current of the incandescent lighting plant, special wires being laid beneath the floors and connected with plug receptacles, which are placed in the base-boards near each bed in the wards, and beneath the lamps in the private rooms. To these receptacles movable tables provided with a meter and rheostat may be attached at will.

The use of this strong current in medical work is made possible by the special form of rheostat, or current controller, devised by Dr. Massey, which consists of a circular pencil-mark arrangement, permitting any gradation of current from a fraction of a milliampère to fifty milliampères, by the simple movement of a lever. The current used, both for this work and for the electric lighting, is derived from an Edco storage battery of sixty volts and slight internal resistance, fed by a dynamo, both being situated in the basement. The franklinic currents are derived from a four-plate twenty-two-inch Toepler-Holtz machine, with a spark capacity of seven inches.

A very interesting and unusual feature of this hospital is a room on the ground floor devoted to such research as requires instruments of precision. There are, of course, apparatus such as thermometers of all kinds, sphygmographic instruments, and others for counting blood-corpuscles and estimating hæmoglobin; mechanical arrangements for studying and recording tremors and knee-jerks; and devices for the study of clonus, on which Dr. Mitchell is now engaged. In the middle of the room is a large kymographion, with the usual arrangements of tuning forks, etc., for the records of small fractions of seconds.

It is the desire of the managers and of the physicians that the numerous researches which have found their means in these clinics in the past, should in the future receive every encouragement. No hospital in America has, we believe, in the last ten years so notable a record of original work done.

We propose shortly to speak of some of the methods in use here in the treatment of disease.

A MEDICAL COLLEGE AT PORTLAND, OREGON.—A medical college has recently been organized in Portland, Oregon, in connection with the Oregon State University. A faculty of thirteen members have been elected.

THE AMBULANCE TRAINING OF RAILWAY EMPLOYÉS.—In view of the recent railway accident in a western State, where help was inaccessible, the success of this movement in Scotland is of interest. The *British Medical Journal* of August 13, 1887, speaks as follows of this new branch of ambulance training:

"One of the most valuable developments of the ambulance movement in Scotland has been in the train-

ing of railway servants. A most interesting meeting took place in Dunfermline on Sunday evening, when sixty-three railway servants who had received training in ambulance were presented by the Earl of Elgin with the certificates of the St. Andrews Ambulance Association, ninety-three having attended the course of instruction. Various speeches were made by well known local magnates on the great value to their own class and to the public which would accrue through railway servants being properly instructed and accomplished in ambulance work. Drs. W. B. Dow and Oliphant Dow also addressed the meeting, they having conducted the class. The Provost of Dunfermline suggested that ambulance appliances should be placed in all railway stations, and a good deal could be said in favor of this idea."

CONTAGION IN LAUNDRIES.—DR. RUSSELL, medical officer of Glasgow, says that during the last ten years over a million of articles (from persons affected with every kind of contagion known in this country) have passed through the Glasgow laundry, and that he has never known a case of interchanged disease, although the women engaged in the laundry have occasionally suffered from handling the linen before the boiling process.—*Popular Science News*, August, 1887.

THE INTERNATIONAL CONGRESS OF HYGIENE AT VIENNA.—The *British Medical Journal* of August 20, 1887, thus describes the prospects of this approaching Congress:

About 1500 members are expected to take part in the proceedings of this Congress, which, as has been already announced, will be opened next month; 1300 persons have already registered their names. Professor Corfield is announced to read a paper on "The Importation of Rags;" Dr. Frankland, on "Sewage," with special reference to the prevention of river pollution; Mr. F. Hayes Whymper, on "The Law Relating to Factories and Workshops;" and Mr. Murphy, on "International Regulations for Preventing Epidemics." The Austrian Government, it is stated, will take a special interest in the labors of the Congress.

INOCULATIONS FOR HYDROPHOBIA IN THE VIENNA GENERAL HOSPITAL.—A request has been presented by the Austrian Chamber of Deputies to the Managers of the General Hospital, asking that preventive inoculations for rabies be made there.

THE PREVENTION OF HYDROPHOBIA IN DOGS.—The report of the Select Committee of the House of Lords on Rabies in Dogs, just issued, is the complement of the report of the Committee on M. Pasteur's system. The latter dealt with the scientific and medical questions raised by the discovery of M. Pasteur; the former deals with administrative measures for the prevention of disease in dogs. The Lords' Committee has done well to insist upon the facts already well known—that the disease is comparatively rare even in dogs, and that but a small proportion of the persons bitten are liable to contract the disease. This aspect of the question has recently been so fully discussed in these columns that it is unnecessary to recapitulate the facts, but it may be stated that the evidence given by experts impressed the Lords Committee with the protective value of immediate cauterization either with the actual cautery or carbolic acid. The administrative improvements recommended by the committee may be divided into those which would have a permanent effect and those which would only be applied during epidemics. The permanent measures recommended are that, in populous places, local authorities should place restrictions on dogs generally, and especially deal stringently with apparently ownerless dogs in their districts; that the symptoms of rabies should be endorsed on dog licenses; and that the local authorities should have power to order that dogs should wear badges which may identify their owners. Those which would have a mere temporary applicability are: That when rabies is prevalent the muzzle should be enforced; that the power of the police-constable should be extended to authorize the slaughter of stray dogs.—*British Medical Journal*, August 13, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM AUGUST 23 TO AUGUST 29, 1887.

SMITH, JOSEPH R., *Lieutenant-Colonel and Surgeon.*—Ordered to report in person to the Surgeon General of the Army, on September 2, 1887, on business connected with the public service, and on completion thereof to return to his proper station. —*S. O. 198*, par. 9, *A. G. O.*, August 26, 1887.

BARTHOLF, JOHN H., *Major and Surgeon.*—Leave of absence extended one month.—*S. O. 196*, par. 7, *A. G. O.*, August 24, 1887.

PATZKI, JULIUS H., *Captain and Assistant Surgeon.*—Granted leave of absence for one month.—*S. O. 195*, par. 15, *A. G. O.*, August 23, 1887.

MATTHEWS, WASHINGTON, *Captain and Assistant Surgeon.* —Ordered to proceed to Phœnix, Arizona Territory, on public business, and on completion thereof to return to his proper station. —*S. O. 195*, par. 21, *A. G. O.*, August 23, 1887.

TAYLOR, BLAIR D, *Captain and Assistant Surgeon.*—Granted leave of absence for twenty days, to take effect on or about August 31, 1887.—*S. O. 193*, par. 7, *A. G. O.*, August 20, 1887.

SWIFT, E. L., *First Lieutenant and Assistant Surgeon.*—Ordered to report in person to the Commanding General, Division of the Pacific, for duty with troops at Round Valley, Indian Reservation.—*S. O. 195*, par. 20, *A. G. O.*, August 23, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING AUGUST 27, 1887.

BAILHACHE, P. H., *Surgeon.*—Granted leave of absence for thirty days, August 26, 1887.

CARTER, H. R., *Passed Assistant Surgeon.*—Granted leave of absence for twenty seven days, August 25, 1887.

YEMANS, H. W., *Passed Assistant Surgeon.*—Resignation accepted, to take effect September 30, 1887, and leave of absence extended to that date, August 24, 1887.

NORMAN, SEATON—Granted leave of absence for six days, on account of sickness, August 27, 1887.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

INTERNATIONAL MEDICAL CONGRESS.

NINTH SESSION, WASHINGTON, 1887.

FEVER:

ITS CAUSE, MECHANISM AND RATIONAL TREATMENT.

An Address delivered in General Session, September 6, 1887.

BY PROF. AUSTIN FLINT, M.D., LL.D.,

OF NEW YORK.

In the classical monograph on inanition, by Chossat, published in 1843, is the following sentence: Inanition is "a cause of death which marches in front and in silence in every disease in which alimentation is not in a normal condition."[1]

A few years later, Graves, of Dublin, insisting upon the importance of alimentation in the management of continued fever, said that if he had met with more success than others in the treatment of the disease, it was owing, in a great degree, to the counsel of a country physician of great shrewdness, who advised him never to let his patients die of starvation.

Nearly half a century has elapsed since Chossat, comparing the results of a series of elaborate experiments on the lower animals with pathological phenomena in the human subject, recognized inanition as a cause of death in diseases which were then treated by depletory and so-called antiphlogistic measures, and since the "shrewd country physician" advised Dr. Graves never to let his patients die of starvation. Within this half-century, the ideas embodied in the two quotations I have made have taken a permanent place among the accepted principles of the science of medicine. The researches of the physiologist enabled him to recognize the spectre of inanition, marching "in front and in silence" with disease, and the great clinical observer "fed fevers;" the natural history of many diseases, undisturbed by active therapeutical measures, has been studied, and the self-limited character of a large number of these diseases has been established; and now, in the treatment of certain cases, abortive measures having been found ineffectual, the resisting and recuperative powers of patients are sustained.

An important result of the studies of physiologists with reference to animal heat, and of pathologists with reference especially to the essential fevers, is that, important organs being protected against serious complications and accidents, and the nutrition of the body being measurably supported, a fever may run its course, leaving the patient in a physical condition in which speedy and complete convalescence is almost certain. The life of an acute disease usually is short; and a self-limited disease, such as typhoid fever, is a morbid force which calls for resistance on the part of the system for but a certain time. In cases of acute disease, as a rule, there is an inherent tendency to recovery. A disease which involves in its course a rapid and abnormal consumption of matter within the body can rationally be met by the introduction and assimilation, if possible, of nutritive material to save or repair the destruction of tissue. That there is abnormal destruction of tissue in fevers is rendered certain by the progressive loss in body-weight and the marked increase in the elimination of carbonic acid and nitrogenized excrementitious matters; and it is the province of the physician to keep this loss within the lowest limits, and to repair it as speedily and as effectually as possible.

The principal object of this address will be to show how the metamorphosis of matter involved in the normal production of animal heat is accomplished, how the abnormal production of heat in fever, involving, as it does, abnormal activity in the metamorphosis of tissue, may be restricted, and how abnormal destruction of tissue may be limited and repaired.

It is well known to physiologists that the production of animal heat is one of the phenomena attendant upon the general processes of nutrition. It is also well known that the process with which the production of heat is most intimately connected is oxidation of certain matters which are either contained in food or form a part of the tissues of the body. This fact, a knowledge of which dates from the researches of Lavoisier, in the latter part of the last century, has now become firmly established; and the relations between the consumption of oxygen—with the production of certain excrementitious matters—and the generation of heat within the body have, in late years, been the subject of much physiological experimentation. Attempts have been made by Senator and others, to measure directly the quantity of heat produced in the body; with the result of showing that, in mammals, there are produced about four heat-units per hour, per pound weight of the body.[1] According to this estimate, a man weighing one hundred and forty pounds would produce 13,440 heat-units in twenty-four hours.

While the direct method of estimating the heat produced by the body has some elements of uncertainty, it has the advantage, at least, of being similar to the method by which the heat-value of food has been ascertained. On the other hand, the indirect method, employed by some observers, which is said by Dr. Foster to be "as trustworthy as any," seems to me to involve such

[1] Chossat: Recherches expérimentales sur l'inanition. Paris, 1843, p. 194.

[1] The English heat-unit represents the heat required to raise the temperature of one pound of water one degree Fahrenheit. The Continental heat unit represents the heat required to raise the temperature of one litre of water one degree Centigrade. One heat-unit, Continental, equals about four (3.9628) heat-units, English. Four heat-units per pound per hour (English) would equal about one heat-unit (Continental) per pound per hour, or 2.2 heat-units (Continental) per kilogramme per hour. In what is to follow, I shall adopt the English standard for the heat-unit.

possibly enormous errors as to be of little value. This method consists in "simply subtracting the normal daily mechanical expenditure from the normal daily income. Thus, 150,000 kilogramme-metres subtracted from 1,000,000 kilogramme-metres, gives 850,000 kilogramme-metres as the daily expenditure in the form of heat."[1] In this method the only reasonably accurate element in the calculation is the "normal daily income," which is ascertained by estimating the heat-value of food in a normal diet. The calculation of the "normal daily mechanical expenditure," is inaccurate almost to the degree of absurdity. The force expended in the circulation and respiration is estimated, the force in locomotion and in other muscular work is guessed at, and all these estimates of expenditure of energy are calculated in foot-pounds, or kilogramme-metres, which are afterwards reduced to heat-units. Taking, the estimate of the work of the heart alone, if Dr. Haughton's calculation of the quantity of blood discharged by each ventricular systole, which is three ounces, be accepted, a certain result is arrived at; while, if we accept—and on equally good authority—the view that the quantity discharged is between five and six ounces, the figures are nearly doubled, and the error is multiplied by about fourteen times at the heart in twenty-four hours.[2] The calculations also of the force used in respiratory movements, locomotion, etc., are not more reliable; and while it is admitted that one pound weight falling 772 feet will turn a wheel, the friction of which will raise the temperature of one pound of water one degree Fahrenheit, no one has been able to raise one pound weight to the height of 772 feet, or 772 pounds to the height of one foot, by using the heat which will raise the temperature of one pound of water one degree. In the calculations applied to physiological processes, it is always the heat produced which is converted into force; and in fixing the formula for such calculations, it is always the force which is converted into heat. It seems to me, therefore, that the most inaccurate of the direct methods of measuring the heat produced in the body is more useful than any calculations which involve such enormous sources of error as must exist in the estimates of daily mechanical expenditure. However, in the reflections that are to follow, I shall have nothing to do with the conversion of heat into force, but shall confine myself to the questions involved in the normal and abnormal production of heat in the human body.

The late Dr. John C. Draper, following the experiments of Senator and others upon the inferior animals, made a series of observations on his own person, in which he showed that his body, which he found was capable, in twenty-four hours, to three cubic feet, was capable of raising the temperature of three cubic feet of water five degrees Fahrenheit in that time. During the observation, the temperature of the room in which he was reduced one degree.[3] Making the correction—which was not made by Dr. Draper—of one degree lost by the body and imparted to the water,[4] I estimated that the body produces four heat-units per pound weight per hour, which is nearly the result obtained by Senator, and that, consequently, a man weighing 140 pounds would produce 13,440 heat-units in twenty-four hours, in a condition of absolute repose. This quantity would, of course, be increased by muscular exercise.

In a series of experiments made upon my own person, for twenty-four hours, under a liberal diet, I calculated the heat-value of the food ingested as equal to 14,079.15 heat-units. At that time (1878), I weighed 180½ pounds, and, according to my estimate, I produced 17,880 heat-units in twenty-four hours. There was no difference in the body-weight at the beginning and at the end of the observation.[5] This observation showed that nearly one-sixth of the heat estimated as actually produced by the body was not accounted for by the heat-value of the food taken. There can be little question with regard to the accuracy of the accepted methods for estimating the heat-value of articles of food; and it follows logically that there must either be a grave error in the estimate of the heat produced by the body, or that there are certain processes going on within the body not taken into account by physiologists, which involve a considerable production of animal heat. It is to be remembered, also, that I made no allowance for the conversion of a certain proportion of the heat produced in the body into force expended in circulation, respiration, locomotion, etc.

Indirect observations have shown that, out of the daily quantity of hydrogen introduced in organic combinations in the food, a large proportion (about eighty-five per cent.) cannot be accounted for by the organic ingredients of the excretions; and it has also been shown that there is generally an excess of water discharged from the body, over that introduced with the food and drink.[6] In another experiment made on my own person, in 1878, I fasted for thirty-three hours, beginning my observations on the discharge of water, nine hours after the beginning of the fast, in order to allow the digestion of the last meal to be completed. In twenty-four hours, the discharge exceeded the introduction of water by forty-six ounces. I calculated the quantity of water discharged, by deducting from the total loss of body-weight the loss of solid matters in the urine and the estimated loss of carbon by the lungs. The quantity remaining represented the loss of water in excess of the water introduced. The quantity of water introduced was twenty ounces. No feces were passed during this observation.

In another observation, the total discharge of water for a period of five days was estimated by the following method:

"The weight of the ingesta for the five days was added to the body-weight at the beginning of the observation.

[1] Foster, Text-book of Physiology. London, 1878, p. 454. A [illegible] Physiology, and Hygiene, p. 1[illegible]

[6] Flint: Experiments and Reflections upon Animal Heat, loc. cit., p. 355.

[7] Dalton: Human Physiology, Philadelphia, 1882, p. 37.

From this were deducted, the weight of the urine and feces for the five days, the estimated weight of carbon eliminated, and the body-weight at the end of the observation. The result represented the total discharge of water by the lungs and skin, which, added to the water of the urine and feces, gave the total discharge of water. From this was subtracted the water introduced in food and drink. The total excess of water discharged for the five days was 62.78 ounces.[1] The subject of this experiment weighed 119.2 pounds at the beginning of the observation. At the end of the five days, having walked 317½ miles, he weighed 115.75 pounds.

The observations thus briefly described seem to show that, under certain circumstances at least, water is actually formed in the body by the union of oxygen with hydrogen. In the observation made fasting for twenty-four hours, the quantity thus formed was very large. If it can be assumed that water is formed in this way, the heat-value of hydrogen being very great, there is little difficulty in accounting for the heat which has been estimated by direct observation to be produced in the body, as well as for a considerable surplus of heat expended in the form of muscular force. The theory, however, that the oxidation of hydrogen in the body is an important factor in the production of animal heat leads to very interesting and somewhat novel reflections with regard to the physiological relations of water to the general processes of nutrition.

Water regarded as a product of excretion. There are two substances that result from the physiological wear of the tissues, which may be taken as typical products of excretion. One of these, carbonic acid, is a non-nitrogenized principle; and the other, urea, is nitrogenized. Both of these principles are produced in the tissues and are carried by the blood to eliminating organs. The excretion of both is influenced by the activity of molecular changes in the body. It is with these principles that I shall compare the water which is, in all probability, formed in the body and discharged, under certain circumstances at least, in excess of the water of food and drink.

An excrementitious substance is a principle discharged from the body and produced by physiological wear, chiefly in the form of oxidation, of the organism. It is probable that the organism, under normal conditions as regards alimentation, use of parts, etc., produces a quantity of excrementitious matter which is fixed between certain physiological limits. When alimentation is excessive, a certain proportion of nutritive matter is represented in an increased discharge of excretions. This is marked as regards both carbonic acid and urea, particularly in the increased discharge of urea under an alimentation containing an excess of nitrogenized alimentary matters. Starch, sugar, fats, and albuminoids are not discharged from the body in health, but are eliminated in the form of carbonic acid, urea, urates, etc., and water. Muscular work increases immensely the discharge of carbonic acid, in a less degree the discharge of urea, and it notably increases the discharge of water.[2] Muscular work also increases the production of animal heat, but the temperature of the body is regulated within normal limits by evaporation from the general surface. When an excess of food is taken habitually and for a long time, there generally results an abnormal accumulation of fat, it being impossible for the elimination of carbonic acid to keep pace with the introduction and assimilation of food, unless there be a large expenditure of heat and force in muscular work. The excess of nitrogenized food is disposed of largely in the form of urea; but it is probable that a certain part of this excess is converted into fat, and the muscular substance cannot be increased in bulk except by exercise, and then only within certain restricted limits.

As compared with carbonic acid and urea, the water produced in the body seems, to a great extent, to be subject to the same laws. It is a product of oxidation within the organism; its production may be influenced by alimentation, independently of the quantity of water introduced, and by muscular work; it is discharged through organs recognized as organs of elimination, such as the lungs, skin, and kidneys; but its chief point of similarity with the matters generally recognized as excrementitious is in its mode of production.

It has been thought that excrementitious principles, if their elimination be interrupted, are of necessity poisonous when retained in the system. This certainly is not true of water; but the opinion upon this point, with regard to principles commonly regarded as excrementitious, is now open to serious question. It is probable that carbonic acid is not in itself poisonous, and that its retention in the blood produces death by interfering with the absorption of oxygen. There are few conditions under which an animal can be placed, in which carbonic acid can be made to accumulate in great quantity in the blood without interfering with the supply of oxygen; but in the well-known experiments of Regnault and Reiset, dogs and rabbits were exposed for many hours to an atmosphere containing twenty-three per cent. of carbonic acid artificially introduced, with between thirty and forty per cent. of oxygen, without any ill effects.[1] It is now thought by some pathologists that the so-called uræmic convulsions are not due purely and simply to the poisonous effects of the retention of urea in the blood, although this is still an open question.

If it be assumed that water is produced *de novo* in the economy, in its method of production, it closely resembles carbonic acid; but it differs from carbonic acid in having certain uses so important as to lead to its frequent introduction with the food and drink. Its chief use, however, as regards nutrition, is as a solvent; but in this it is aided by carbonic acid, the presence of which, especially in the urine, increases the solvent properties of the liquids of the organism. It is evident, also, that water, as a constituent part of the tissues, tends to preserve their proper consistence.

The water of food and drink has important indirect uses connected with nutrition, both as a solvent of nutritive and excrementitious matters and as a constituent part of the tissues; but the water produced

[1] Flint: Human Physiology, N. Y., 1884, pp. 516, 517.

[2] Pettenkofer and Voit: Journal of Anatomy and Physiology, Cambridge and London, 1868, vol. ii. p. 181. "The elimination of water is very much increased by work, and the increase continues during the ensuing hours of sleep." This was one of the conclusions arrived at from experiments upon a man, twenty-eight years of age, kept for twenty-four hours in a large "respiration apparatus."

[1] Annales de chimie et de physique, Paris, 1849, 3me série, tome xxvi.

within the body by the union of oxygen with hydrogen behaves, in the manner of its production and elimination, like an excrementitious matter.

If this view be accepted, it is evident that the two excrementitious principles, with the production of which the generation of animal heat is most closely connected, are water and carbonic acid. Under ordinary conditions of alimentation, the production of carbonic acid probably has the greater relative importance; but in starvation, while the excretion of carbonic acid is diminished, the production of water, as shown in my starvation-experiment, is probably very largely increased. It is evident that the production of carbonic acid is a much more important factor in the generation of animal heat than is the formation of urea. In the experiment referred to, I calculated the heat-value of the urinary nitrogen as equal to 1677.70 heat-units, and the heat-value of the carbon eliminated as equal to 10,759.09 heat-units. The deficiency, as regards the heat actually produced, must have been represented by the excess of water discharged, which amounted to forty-six ounces, the hydrogen of which has a heat-value equal to 19,751.75 heat-units.[1] Persons exposed to intense cold, as in the Arctic regions, are known to require enormous quantities of food rich in fatty matters;[2] and the production of carbonic acid is probably very greatly increased, although direct observations on this point are wanting.

The foregoing remarks on the physiology of animal heat have been simply preliminary to a discussion of fever; and the influence of the nervous system upon calorification, which is so important in disease, will be considered only in its pathological relations.

The mechanism of fever. The phenomena and mechanism of fever in all its varieties constitute much too large a subject for full discussion within the proper limits of this address. It has been rendered probable by recent bacteriological studies that all of the essential fevers are due primarily to the presence of microorganisms, those producing typhoid fever, especially, having been isolated, cultivated, and accurately described. Fevers symptomatic of local inflammations will form no part of the question now under consideration; and I do not propose to take up the question of pyrexia due to exposure to external heat, as in insolation. The condition which I shall consider, as the type of fever, is the pyrexia in typhoid fever, produced by a definite microorganism and having a duration restricted within certain limits which do not present very wide variations. Typhoid fever is strictly an essential fever, producing, like other fevers, certain parenchymatous degenerations and certain secondary effects upon the nervous system; but it is only the nature, mechanism, and rational treatment of the fever itself which I propose to discuss.

The cause of the pyrexia in typhoid fever is twofold. The more important factor is an exaggeration of the chemical changes taking place in the organism, which generate the animal heat within normal limits. A less important factor is a disturbance of the processes of equalization of the heat of the body mainly by the action of the skin. That an exaggeration of heat-producing processes within the body is an important element in the production of fever, is rendered certain by the excessive consumption of oxygen and discharge of carbonic acid and urea. In health, the discharge of carbonic acid and urea is compensated by the introduction of food, which also has a certain influence upon the quantities of these substances eliminated. In health, there are important influences, also, which depend upon muscular work and activity. In an essential fever, the heat-producing processes seem to be for the time removed from normal regulating influences. Even when no food is taken, the fever continues and the excessive discharge of carbonic acid and urea progresses. The regulating action of the skin is enfeebled or absent. In a fever in which no attempt is made to support the system by alimentation, the phenomena of inanition are added to those of the pyrexia. Simple inanition in a healthy subject is marked by a diminution in the excretion of carbonic acid and urea, with a lowering of the animal temperature, and there is usually but little muscular work. In an essential fever, it seems as if the body were at work, producing an excessive discharge of excretions, without adequate compensation by sufficient alimentation and without a proper regulation of the heat of the body by cutaneous transpiration. Assuming the failure of measures employed to abort the disease, the excessive waste of tissue pursues its course until the morbid processes are arrested by self-limitation, or until the patient dies, either from secondary effects, referable to the persistence of very high temperature, or from simple asthenia. In cases of death from uncomplicated typhoid fever, there usually is very great emaciation.

The waste of the organism usually is most marked as regards the adipose tissue, the destruction of which is probably represented in greatest part by the excessive discharge of carbonic acid. The muscles, also, undergo degeneration, which is at first of the variety called parenchymatous. The destruction of the muscular tissue is probably represented in greatest part by the excessive discharge of urea.

If we can logically view water formed in the body in the light of an excrementitious product, the formation of which in health is closely connected with the process of calorification, the changes noted in most of the cases of typhoid fever, as regards the production and discharge of water, become very important. In nearly all essential fevers there is thirst, but the discharge of water by the skin and kidneys is notably diminished, especially the discharge by the skin, which is dry and hot. In health, the formation of water, with its inevitable generation of heat, seems to carry with it the conditions for equalization of the animal temperature by cutaneous transpiration. In simple inanition, the tissues of the body are economized by the excessive formation of water and the increased prominence of this process in calorification. In health, when there is excessive muscular exertion, there is an increased discharge of water, as was noted by Pettenkofer and Voit. In fever, however, the fats and solid tissues undergo destruction

[1] The temperature under the tongue at the beginning of the twenty-four hours of the observation was 98° Fahr. At the end of the twenty-four hours it was 97.4°.

[2] The late Dr. Hayes stated that on one occasion he saw an Esquimaux consume ten pounds of walrus flesh and blubber at a single meal. (American Journal of the Medical Sciences, Philadelphia, July, 1870.)

and certain degenerations. The formation of water seems to be diminished, and certainly there is a diminished discharge of water from the body attending the increase in the discharge of carbonic acid and urea. Whatever be the essential cause of the pyrexia, the consumption of matter in the production of the excessive heat is chiefly of fat and muscular tissue; presenting a striking contrast to the process of calorification in simple inanition and in violent muscular exertion, which latter condition would actually raise the temperature of the body, were it not for the increased formation of water and the cutaneous transpiration. It would seem that in health, when there occurs any unusual demand for heat to be used in muscular work, the production of water, as well as of carbonic acid, is increased; while, in fever, the pyrexia is fed, so to speak, by the fatty and solid tissues of the body alone. In health, muscular work confined within normal limits induces nutritive activity and improved assimilation of food. In fevers, the activity is mainly degenerative and the assimilative processes are seriously impaired.

These considerations lead naturally to some modification of accepted views with regard to the theories of fever, and render our ideas on these questions more positive and definite than heretofore. I shall express these ideas in the form of propositions, some of which are, to a certain extent, novel:

1. It is probable that the original cause of most, if not of all the essential fevers is a microörganism, different in character in different forms of fever.

This proposition is based upon bacteriological researches of recent date, especially with regard to typhoid fever.

2. Defining fever as an abnormal elevation in the general temperature of the body, the pyrexia is due to the following modifications in the normal heat-producing processes:

A. Oxidation of certain constituents of the tissues, probably by reason of the presence of microörganisms in the blood, is exaggerated independently of increased muscular work and without being compensated by a corresponding increase in the appropriation of nutritive material. This increased waste of tissue is represented by the excess of carbonic acid and urea excreted.

B. The part which the formation of water within the body plays in the production of heat is either suppressed or is greatly diminished in prominence, together with the equalizing action of cutaneous transpiration.

This proposition is based upon clinical facts, which show an increased excretion of carbonic acid and urea and a diminished excretion of water in fevers, and upon experiments which show that muscular work, while it increases heat-production, increases the production of water.

3. Fever produces abnormal consumption of fat, with parenchymatous degenerations, for the following reasons:

A. The fat is consumed because it feeds the pyrexia more readily than do the other tissues of the body, and its consumption is the most important source of carbonic acid.

B. Parenchymatous degenerations of muscular tissue and of the solid organs occur, chiefly because the abnormal transformations of these parts, which result in an excess of urea and which probably, also, contribute to the excess of carbonic acid, are not compensated by the appropriation of nutritive matters from the blood.

C. It is well known that patients with unusual adipose or muscular development are likely to present a more intense pyrexia in fevers than are those whose adipose and muscular development is smaller.

Finally, *An essential fever is an excessive production of heat in the body, induced by a special morbific agent or agents, and due to excessive oxidation, with destruction of the tissues of the body, and either a suppression or a considerable diminution in the production of water.*

Suppression or great diminution of cutaneous transpiration in the essential fevers, while it contributes, in a measure, to the rise in temperature, is not itself a cause of fever.

I do not propose to discuss at length the influence of the nervous system on the normal production of heat or upon fevers. It is well known that the nervous system is capable of modifying the local circulations and of producing local changes in temperature. Some physiologists have endeavored to locate a heat-centre, as well as a vasomotor centre, and some varieties of fever are regarded as due to morbid action of nerve-centres, either direct or reflex. A consideration of these questions, except in so far as the nervous system is secondarily affected in fevers, would extend this address beyond its proper limits. I shall, however, allude to certain conditions of the nervous system in fevers in connection with what I shall have to say on the subject of treatment.

Rational treatment of fever. Symptoms referable to the nervous system are nearly always more or less prominent in essential fevers of a grave character. In the great majority of cases, at least, the disturbances of the nervous system are secondary and are due to the pyrexia, being intense generally in proportion to the intensity of the fever itself. While the special morbific cause of typhoid fever is, of course, the cause of the delirium, coma vigil, hebetude, etc., observed in rave cases, it is rational to suppose that it acts as a secondary cause of these phenomena, by virtue of changes induced directly by the prolonged elevation of body-temperature; and the same may be said of the pulse, which is high usually in proportion to the intensity of the pyrexia. Certain it is, that a mere reduction of the temperature, by means which can not be presumed to affect the special cause of the disease, is nearly always attended with an amelioration of the nervous symptoms and a reduction in the rate of the pulse.

The parenchymatous degenerations and the alterations in the structure of the muscles and of the secreting cells of glands are unquestionably due to modifications in nutrition produced by the action of microorganisms; and it is well known that in typhoid fever and in pneumonic fever these microörganisms are deposited in special parts, as the intestinal glands and the lungs. It is certainly a rational object of treatment to confine these degenerations within the narrowest possible limits.

While it is not possible exactly to limit different measures of treatment to particular phenomena, there are certain therapeutical indications specially called for by morbid processes which relate to different systems

and organs of the body. These measures may be classified as follows:

1. Reduction of the general temperature by the external application of cold.

2. Reduction of temperature by the internal administration of antipyretics.

3. Promotion of general nutrition by alimentation.

4. Measures to supply to the system matters that can be consumed in the excessive production of heat, thereby retarding destruction of tissue.

The application of cold to the surface by means of cold baths, sponging, etc., is now almost universal in the treatment of the essential fevers. While the value of this therapeutical measure is undoubted, and while its employment of late years has unquestionably diminished the fatality and abridged the duration of typhoid fever, writers are not agreed upon an exact explanation of its mode of action.

If the proposition that fever is due to the excessive production of heat be accepted as true, the explanation of the modus operandi of the beneficial effects of refrigeration of the surface in fever seems to me to be very simple and entirely satisfactory.

In health, when the body is subjected to excessive cold, the normal temperature is maintained, not only by retaining the radiation of heat from the surface by appropriate clothing, but by an actual increase in the production of heat. External cold increases the consumption of oxygen and the production of carbonic acid. The increased production of heat is promoted by muscular exercise, and the material necessarily consumed is supplied by what, under ordinary conditions, would be an excessive assimilation of food, particularly of fatty matters, which have a high heat-value. The enormous consumption of fats in excessively cold climates is an evidence of this fact.

In fevers, there is an excessive production of heat, which raises the temperature of the body, partly for the reason that the equalizing action of cutaneous transpiration is impaired. If we remove part of this excessive heat by the application of cold to the surface, the temperature of the body is necessarily reduced, and it only remains for clinical observation to determine whether or not this reduction of temperature be beneficial. Its beneficial effects, however, are unquestionable.

Physiological and pathological conditions are thus brought into striking contrast, and the pathological phenomena are readily explained in accordance with physiological principles.

In the healthy body exposed to excessive cold, we have given the condition of cold. This is met by a physiological increase in the processes of calorification, and by vaso-motion of the surface against loss of heat.

In the organism affected with fever, we have given, as a pathological condition, an increase in the processes of calorification. This is to be met by artificial external vaso-motion of cold, the excess of heat is abstracted from the body.

The clinical thermometer, the general condition, and the subjective sensations of patients are safe guide with regard to the extent to which external cold should be applied in any individual case; and the application of cold to the surface is not only a rational measure of treatment in fever,

The amelioration of the nervous symptoms and the reduction of the pulse-rate, which usually follow reduction of temperature by external refrigeration, are arguments in favor of the view that these symptoms are mainly due to the pyrexia itself and not to the direct action of the special morbific agent which produces the disease.

Analogous effects are produced, although in a different way, by internal antipyretic remedies, of which antipyrin and antifebrin are now extensively used in this country in the treatment of fevers. The mode of action of antipyrin is not well understood, but its efficacy and value in reducing temperature are universally acknowledged. Extended and complete observations on the influence of this drug upon the elimination of excrementitious principles are as yet wanting, but the recent experiments of Umbach, in Berne, show that antipyrin has an important action in diminishing the excretion of nitrogen.[1]

Alimentation in fever. It is in accordance with accepted views concerning the physiological production of animal heat and its exaggeration in pyrexia, to supply food in fever, in such quantity as can be readily digested and assimilated, with a twofold object. The only possible objection to alimentation within the limits of assimilation would be clinical experience showing an increase in pyrexia or in other morbid symptoms; but clinical experience shows, on the contrary, that innutrition adds to the intensity of all the morbid phenomena characteristic of the disease. There is no disease in which the spectre of inanition is more prominently "a cause of death which marches in front and in silence" than in typhoid fever. An unusual physiological demand for heat is met by increased alimentation. The pathological increase in the production of heat in fever is attended eventually by destruction of tissue and results in degenerations.

The more prominent and important object of alimentation in fever is to supply or retard waste of tissue and degenerations. In so far as this end is attained, the ravages of fever are restrained. The disease having pursued its course, in proportion as its effects upon nutrition are restrained, the system is better prepared for rapid and complete convalescence.

A second object in alimentation, less prominent and important merely because more difficult and uncertain in practice, is to supply material for consumption, and thus far save destruction and degeneration of tissue.

The extent to which alimentation, therefore, is to be carried is limited only by the powers of the digestive system. Unfortunately, however, the degenerations and disturbances of function, which occur in fever, are prominent in the digestive organs. It is seldom, if ever, possible for a patient to assimilate food in sufficient quantity to repair the waste of tissue; but it is rational to endeavor to secure as much assimilation as is practicable. The difficulties in the way of efficient alimentation are due to degenerations of the glands of the

[1] Archiv für experimentelle Pathologie und Pharmakologie, Leipzig, 1887, Bd., xxi. Nos. 2 u. 3. According to these observations: "Antipyrin, like quinine and other antipyretics, materially lessens the elimination of nitrogenous matters, and can therefore be said to cause a decrease in the tissue changes of the respiratory and alimentary systems." Therapeutic Gazette, Detroit, September 15, 1886.

stomach, to which are frequently added, degenerations of the secreting cells of the salivary glands and pancreas. The practical skill of the physician is taxed to the utmost, in individual cases, to overcome these difficulties; but the judicious administration of milk, eggs, farinaceous articles, meat-broths, meat-essences, etc., is always productive of good results. A part of the nutritive constituents of these articles goes to repair the waste of tissue, and it is logical to conclude that a part supplies matter consumed in the production of heat. It is also rational to assume that, the repair of tissue being carried to the greatest possible extent, the hydrocarbons and fats must be useful in supplying material for those processes which are represented by the excessive elimination of carbonic acid. In no case of fever is it possible actually to accumulate fat in the system during the progress of the disease; and hydrocarbons and fats introduced must contribute to the formation of heat and thus restrict parenchymatous degenerations.

The disturbances which follow an alimentation carried to a degree beyond the powers of the digestive organs afford a reliable guide as regards the extent to which food should be introduced in fevers; and, in my judgment, too little attention and care have been given to the administration of articles of food which have a high heat-value, such as fatty and farinaceous articles.

As a digression, bearing, however, upon the question of the value of fats in conditions involving excessive production of heat, I may allude to their use in pulmonary phthisis.

I assume it to be settled that phthisis is produced by a special microörganism. One of the most prominent general phenomena of phthisis is a constant elevation in the body-temperature. When the disease is progressive, there is an increase in the heat of the body. When the disease is non-progressive, as indicated by physical signs, arrest of loss, and perhaps increase of weight and absence of bacilli from the sputum, the temperature of the body becomes nearly or quite normal. The pyrexia in phthisis is ordinarily not sufficiently intense to induce, of itself, serious disorders of digestion or much general disturbance; and the difficulties in the way of the assimilation of fats are usually not great. Leaving out of consideration, for the present, the effects of alcohol, there is no measure in the treatment of phthisis of greater recognized therapeutical value than the administration of fats.

The use of alcohol in fever. Alcohol is a substance, the toxic effects of which, taken in excess, are quickly and distinctly manifested; and there are few agents more prompt and decided in their influence in cases of disease. Clinically, the effects of alcohol in diseases in which there is a tendency to death by asthenia are so marked, that it is often used indiscriminately and injudiciously. In the treatment of fever the immense benefit which follows the use of alcohol in certain cases has led, at one time, to its use under all circumstances; and its indiscriminate administration, on the other hand, has produced, from time to time, a reaction of opinion, leading to its suppression in cases in which it would be of great service. Many of the moral arguments against the use of alcohol in disease are entirely illogical, and could, with equal want of propriety, be applied to a number of important articles of the materia medica. Alcohol is a potent agent in the treatment of fever; and the clinical guides which should direct its administration are easily recognizable.

In no case of disease, except, perhaps, in certain instances of poisoning by animal venoms, should alcohol be administered to a point where the slightest degree of alcoholic intoxication is apparent.

Alcoholic intoxication is due to certain peculiar effects of alcohol upon the nerve-centres; and in order to produce these effects the alcohol must circulate in the blood. As these effects pass off, the alcohol is either oxidized or is eliminated by the skin, lungs, and kidneys. Under normal conditions of nutrition, the effects of alcohol are so rapid and transitory, and are followed by such decided reaction, that it contributes little or nothing toward a prolonged resistance to cold. Experience has shown that it cannot take the place of an abundant and a highly fatty alimentation in excessive cold, as in the Arctic regions; and under these conditions its constant use has been found to be positively injurious. The same remark is in a measure applicable to all conditions of healthy nutrition. In a continued fever, however, the conditions are radically changed. In accordance with the views which I have presented, the excessive production of heat in fever is a fixed condition, continuing for a certain period, which is limited by the duration of the disease. The phenomena referable to the pulse, to the nervous system, etc., are secondary to the pyrexia. The parenchymatous degenerations are the more remote changes of tissue which follow and result from transformations involved in the long-continued excessive production of heat. If these views be accepted as correct, any readily oxidizable substance artificially introduced, will, if it be oxidized, mitigate the secondary effects of the fever upon the pulse and nervous system and retard degenerations, provided, always, that it do not increase the intensity of the pyrexia. Experience is not wanting to show that these results follow the judicious administration of alcohol in fever.

Inanition is also a constant element in a fever long continued. In health, the formation of water in considerable quantity, in the production of heat, occurs in the first part of a period of deprivation of food, and this saves, to a certain extent, destruction of the solid tissues. One of the most marked and constant conditions in fever is a disturbance of the heat-producing processes, in which the solid tissues are consumed and the production of water is greatly diminished. It is a rational object of treatment to endeavor to restore the normal equilibrium between the consumption of the so-called solids and the formation of water, as factors in the production of heat. If it were possible to introduce farinaceous and fatty articles of food in sufficient quantity in fever, it might not be necessary or desirable to use alcohol; but the condition of the digestive organs is such that these articles are slowly and imperfectly prepared for absorption. Alcohol, however, requires no preparation by digestion. It is promptly taken up by the blood, and is oxidized even more readily in fever than in health.

It is well known that saccharine and starchy articles of food, as well as the liver-sugar, rapidly disappear, and that starch is converted into sugar in digestion. In a remarkable paper by Dr. William Hutson Ford, a number of interesting experiments are published, showing the presence of alcohol in small quantity in the normal

blood, resulting according to Dr. Ford, from the decomposition of sugar. In this paper, Dr. Ford makes the following statement:

"The destruction of alcohol, whose presence in the economy I have thus demonstrated, must be to a hæmal oxidation or 'combustion,' as a main source of animal heat. This combustion is maintained, not only by glucose derived from amylaceous food, but likewise from the proximate products of change in the nitrogenous tissues."[1]

The thermal phenomena observed in diabetes mellitus are of much interest in connection with the theory that hydrocarbons are converted into alcohol, the oxidation of which is an important factor in the production of animal heat. In nearly all cases of diabetes there is a constant and persistent depression of the animal temperature. The principal pathological condition in this disease is manifested by a discharge from the body, in the form of sugar, of the hydrocarbonaceous elements of food; and, as a consequence, these substances are not used in the production of heat. The result is a constant depression in temperature, with a loss of weight which is often very rapid, due to a consumption of the fatty and nitrogenized parts of the tissues, and certain parenchymatous degenerations which are observed particularly in the cells of the kidneys. It may seem paradoxical to say that diabetes is attended with a fever in which the temperature of the body is depressed. In progressive phthisis there is usually a fever, marked by elevation of temperature. It destroys the fatty and nitrogenized parts are consumed to an abnormal extent, as in fever, but the heat-producing action of the hydrocarbons being suppressed, even this excessive consumption of fats and albuminoids is inadequate to maintain the normal standard of the bodily temperature. The theory that the hydrocarbons are converted into alcohol which is oxidized in the body is entirely reconcilable with my view of the production of water as an important factor in the generation of animal heat. If alcohol be oxidized in the body, as it is in certain quantity, the production of water is inevitable. The heat-value of the hydrogen in alcohol being very great, and if—the hydrocarbons being discharged in the form of sugar in diabetes—the normal heat of the body be not maintained, the final oxidation of these hydrocarbons, with the consequent production of water, is an important factor in the production of animal heat. The excessive quantity of water discharged in diabetes probably represents a great part directly from the blood and the watery portion of the tissues, which accounts for the intense thirst always observed in grave cases of this disease.

In the administration of alcohol in the treatment of fever, we are really using the hydrocarbons in a form in which they may be immediately oxidized and do not require preparation by digestion. Thus we easily supply material to meet the excessive waste involved in the pyrexia, in much the same way as we administer peptonized albuminoids to meet the excessive waste of the nitrogenized parts of the tissues when the digestive powers are impaired.

It is a matter of universal clinical observation that there is great tolerance of alcohol in fevers and in pulmonary phthisis. This tolerance of an agent which is probably never useful in perfect health is strong evidence of a demand on the part of the system for the class of alimentary principles, the hydrocarbons, which alcohol represents; and it affords an absolute guide as regards the quantity that should be employed. The quantity which will be useful in individual cases may be small or it may be great. In certain exceptional cases, one or two ounces of spirit may be administered hourly for a day or two, with the best results; and this quantity may be taken without the slightest manifestation of alcoholic intoxication. With an alarmingly high temperature, a rapid and feeble pulse, and grave ataxic symptoms indicating impending death, alcohol may be given largely, but never to the extent of producing its characteristic toxic effects. In fever only such quantity of alcohol as is readily oxidized is useful; and any excess, which will certainly produce some degree of alcoholic intoxication and which must be eliminated as alcohol, will be productive of harm. In ordinary cases of continued fever it is seldom necessary or desirable to give more than eight or ten ounces of spirit daily.

I do not wish to be understood as advocating an indiscriminate use of alcohol in all cases of fever. Alcohol is indicated by an excessively high temperature, with the ataxic and other symptoms to which I have referred. In ordinary cases of typhoid fever, particularly in the early stages, it should be administered sparingly, cautiously, and tentatively. Its quantity should be reduced on it should be omitted at the first indication of alcoholic intoxication. Nevertheless, alcohol, judiciously administered, so that all that is introduced is promptly and completely oxidized, as it contributes material for consumption in the production of excessive heat, exactly in that degree does it retard destruction and degeneration of tissue, and it should be employed to supplement the use of matters that are regarded as nutritive.

In a paper published in 1879, I made a calculation of the heat-value of the ordinary brandy of the pharmacopœia, which I venture to quote:

"According to Brande,[1] cognac brandy contains 46 per cent. of absolute alcohol. With a specific gravity of 0.930, one ounce of brandy weighs 406.875 grains and contains 187.1625 grains of alcohol. The alcohol, with a composition of $C_2H_6O_2$, contains 12.9 per cent. of hydrogen, or 24.14 grains, and 56.65 per cent. of carbon, or 98.54 grains. The heat-value of 24.14 grains of hydrogen equals 214.77 heat-units. The heat-value of 98.54 grains of carbon equals 182.44 heat-units.[2] Taking, then, the total heat value of the hydrogen and car-

[1] Brande and Taylor: Chemistry, Philadelphia, 1857, p. 883.

[2] Mayer: Celestial Dynamics, Correlation and Conservation of Forces, N. Y., 1868, p. 261.

bon contained in one ounce of brandy, and taking no account of the oxygen contained, the heat-value amounts to 397.21 heat units.[1] If we assume that a man produces four heat units per pound weight of the body per hour, the amount of heat normally produced in twenty-four hours by a man weighing 140 pounds is equal to 13,440 heat units. The quantity of brandy required to supply this amount of heat, according to the calculations I have just made, would be a little less than 34 ounces. Theoretically, then, it is easy to see how alcohol may furnish material to supply heat and save waste of tissue in fevers. It is not very unusual in certain stages of fever, to administer from 16 to 32 ounces of brandy in twenty-four hours."[2]

I am deeply sensible of the great honor of an invitation to address this Congress. This invitation I felt bound to accept, although with a full appreciation of the responsibility which it involved and with much doubt and timidity with regard to my ability to do even a small measure of justice to the occasion. I have selected a topic of great present interest, which has been the subject of much fruitful study within the last few years. In discussing this subject, I have endeavored to apply the physiological methods of study which have lately contributed so largely to the advancement of pathology and therapeutics. I have been led by my reflections upon animal heat and fevers to present certain views which I venture, in conclusion, to summarize in the following propositions:

1. Fevers, especially those belonging to the class of acute diseases, are self-limited in their duration, and are due each one to a special cause, a microörganism, the operation of which ceases after the lapse of a certain time.

2. We are as yet unable to destroy directly the morbific organisms which give rise to continued fevers; and we must be content, for the present, to moderate their action and to sustain the powers of resistance of patients.

3. The production of animal heat involves oxidation of parts of the organism or of articles of food, represented in the formation and discharge of nitrogenized excrementitious matters, carbonic acid and water.

4. As regards its relations to general nutrition and the production of animal heat, water formed in the body by a process of oxidation is to be counted as an excrementitious principle.

5. Fever, as observed in the so-called essential fevers, may be defined as a condition of excessive production of heat, involving defective nutrition or inanition, an excessive production and discharge of nitrogenized excrementitious matters and carbonic acid, with waste and degeneration of the tissues, and partial or complete suppression of the production and discharge of water.

6. Aside from the influence of complications and accidents, the ataxic symptoms in fevers, the intensity and persistence of which endanger life, are secondary to the fever and are usually proportionate to the elevation of temperature. These symptoms are ameliorated by measures of treatment directed to a reduction of the general temperature of the body.

7. The abstraction of heat by external cold and the reduction of temperature by antipyretics administered internally, without affecting the special cause of the fever, improve the symptoms which are secondary to the pyrexia.

8. In health, during a period of inanition, the consumption of the tissues in the production of animal heat, is in a measure saved by an increased production and excretion of water.

9. In fever, the effects of inanition, manifested by destruction and degeneration of tissues, are intensified by a deficient formation and excretion of water.

10. Alimentation in fever, the object of which is to retard and repair the destruction and degeneration of tissues and organs, is difficult mainly on account of derangements of the digestive organs; and this difficulty is to be met by the administration of articles of food easily digested or of articles in which the processes of digestion have been begun or are partly accomplished.

11. In the introduction of the hydrocarbons, which are important factors in the production of animal heat, alcohol presents a form of hydrocarbon which is promptly oxidized, and in which absorption can take place without preparation by digestion.

12. Precisely in so far as it is oxidized in the body, alcohol furnishes matter which is consumed in the excessive production of heat in fever, and saves destruction and degeneration of tissue.

13. The introduction of matters consumed in the production of heat in fever, diminishes rather than increases the intensity of the pyrexia.

14. As the oxidation of alcohol necessarily involves the formation of water and limits the destruction of tissue, its action in fever tends to restore the normal processes of heat-production, in which the formation of water plays an important part.

15. The great objects in the treatment of fever itself are to limit and reduce the pyrexia by direct and indirect means; to limit and repair destruction and degeneration of tissues and organs by alimentation; to provide matters for consumption in the abnormal production of heat; and thus to place the system in the most favorable condition for recuperation after the disease shall have run its course.

[1] It is well known that the heat-value of certain elements in combination is less than of the same elements in a free state, as was shown by the experiments of Favre and Silbermann, made many years ago; but with regard to alcohol, the difference is only about one-third of one per cent. Favre et Silbermann: Annales de chimie et de physique, 3me série, Paris, 1842, tome xxxiv. p. 357, and Milne Edwards: Leçons de physiologie, Paris, 1863, tome viii. p. 25.

THE EXPERIMENTAL METHOD IN SCIENTIFIC MEDICINE AND ITS RELATIONS TO BACTERIOLOGY.

An Address delivered in General Session, September 7, 1887.

By PROFESSOR MARIANO SEMMOLA,
OF NAPLES.

Gentlemen: Honored by an invitation to deliver before you a General Address, I feel at once the duty of expressing to you my recognition of an honor superior to my modest merit, and I am obliged to ask your indulgence in the task, since I desire rather to bring to you the greeting, entrusted to me by my Government,

than to appear as worthy to take a prominent part at this feast of medical science. In the name of Italian Medicine, I greet you, my illustrious colleagues of the United States, representatives of the progress of medicine in the New World; and first, I thank you for the courtesy with which you have received me.

An humble son of Italy, I have always longed to see Italian medicine adorned with its worthy title, therefore, when invited, by your country, to address you, I thought I could best merit the esteem of scientific men, and prove myself a worthy child of Italy, by demonstrating one of the greatest discoveries of modern medicine, namely, the experimental method, which was born with Galileo, in Italy, and which has been the only loadstone of her scientific discoverers.

On the banner of ancient medicine was inscribed the motto "Conserve strength and cure disease." This motto should be the talisman of every student of medicine to guard him from the evils of idle, but scientific curiosity. It is easy to see that because there are sick there are physicians, and this continued existence of both classes has occasioned the sarcasm, "Physician, heal thyself," which fully expresses the irony of public opinion regarding unsuccessful medicine. I can conceive of a physician or chemist who is not an artisan, or a botanist who is not an agriculturist, but I cannot conceive of a physician who does not study to cure the sick, because a physician's study is inexorable, and, also, is his true and only mission; for myself and other thinking men, the true test of medical progress is the great or small number of patients rescued from death. This standard may seem prosaic, but it is the bare truth, and this truth renders medicine one of the most important factors in civilization, because wherever men strive for a common aim, medicine is a common interest. "Mens sana in corpore sano" is the true expression of human felicity. Whatever man's condition, his greatest care is to preserve strength and life; sickness and death represent disorder, anguish, and desolation in the household. Family ties are ties of a community, and the death of an individual may alter the destinies of a nation.

In no other branch of science is there so ardent a desire to solve unsettled problems as in medicine. We naturally hope to reach the solution of the problems of healthy and morbid activity, and this hope ever reappearing, has inspired mankind through all ages, and will do so in the future. From Hippocrates to Koch and Pasteur, from the age when man believed himself to possess the knowledge of the Infinite to the present, when analytical research threatens to extinguish all sentiment, for twenty centuries the human mind has struggled through a maze of misapplied reasonings, until it has emerged into the clear light of a critical observation and positive scientific and experimental research. Actual progress in physical and chemical science began in the seventh century, when those discoveries were made which rendered possible the subsequent development of biology as one of the experimental sciences, a development destined to save medicine from the wreck which had befallen other branches of human knowledge. After centuries of darkness a light dawned, destined to guide the steps of the votaries of medical science. This beacon light, gentlemen, was experiment, the objective method as contrasted with introspection and deduction. As Bertholiet has said: "The world is not to be conceived by guessing, but by observing." The progress of experimental science is an epic poem whose chief actor is humanity subduing nature.

When evolution pauses, revolution starts the onward march, and such excessive energy may be tolerated when in science or in politics the occasion demands; but natural evolution is consecutive as well as progressive, and he who would push onward must stop within the bounds of natural evolution. This harmony of evolution and revolution is the law of the existence of good and evil, a principle underlying not only science, but the very being of humanity in its different phases. Medicine, like the other sciences, has attacked the innermost citadel of nature, and demands the secrets of life and death; she aspires to mathematical precision, and would enunciate laws whose observance shall be binding upon her votaries. What a golden age for humanity will be the consummation of this hope! It will not be said of medicine then: "Ars medendi, sed ars semper sanandi." He whose therapy fails to reach this point has failed in attaining the object of his art and walks in fruitless quest, attaining nothing; such is history's teaching. The early traditions of therapeutics have preserved to us, through the ages, the first treasures of medicine in mercury, quinine, and iodine; nor have all the discoveries of modern medical science equalled in the treatment of some of the most severe diseases, this foundling child of empiricism. *We affirm, then, that the experimental method in medicine has for its purpose the determination of the phenomena of nature and their causes.* The experimental method admits no individual dogmatic authority, nor has it anything in common with the theories of hypothetical methods. The individual loses his personal authority in comparison with the teachings of demonstrated science. As Goethe has well said: "There is no channel of communication between mind and matter but experience."

Observation and coördination of facts and the formulating of laws is the natural sequence. The experimental method is composed of three elements, observation, the formation of hypotheses, and their verification. The individual often hastens to spread abroad a new discovery, not waiting to prove it, thus injuring, by his premature action, the cause of truth which he seeks to serve. Pascal has described such men by saying: "They never seek causes themselves, but only the way of finding them." Ostrich-like, the framer of a false hypothesis in science hides himself behind the confusion of ideas, while his failure is apparent. Medicine then must proceed in the path which we have narrated, if it will regenerate itself; from this rule there are no concessions, no exceptions. Finally, there must be either empiricism old or new, or an experimental science.

The problem assigned to medicine is very simple; to determine the conditions of vital existence and its phenomena in healthy and diseased organisms. It is not my purpose to describe the application of the experimental method to physiology, by which so many facts of clinical importance have been ascertained. To reach this degree of certainty, it needed more than half a century of study, without counting the precious foundations which biology had prepared for it since the last century. It is sufficient to remember that from the biological chemistry of the blood we now know little or

nothing at the utmost; and the ontological notions which seem to be most correct, are threatened by a revolution since the recent researches of Angelo Mosso, a son of Italy. And we have probably to begin anew.

Scientific and experimental medicine proposes to itself to discover the conditions of existence of the phenomena belonging to life, or to regulate the determination of them, and these are to be the columns of Hercules. Medicine, like all other sciences, never demands why, well knowing that the first causes of things are inaccessible, and that to every scientist it should suffice to know in which physical and chemical conditions this or that phenomenon manifests itself, so that he can modify and govern it at his will.

Which are the phenomena that the physician studies? The answer is the functional disturbances or symptoms of sickness. What are the physical and chemical conditions of these phenomena? The natural causes of the sickness? This is the most simple form of the pathological problem. To arrive logically at the third part of the solution, is the most difficult: that is to say, how can these physical and chemical conditions be artificially modified in disease to reproduce normal physical and chemical conditions, or to make disappear the phenomena of disease and cause a return of the normal functions? It is enough, generally, to announce this series of problems to discourage investigations. This honest confession would appear to me the best introduction to the future scientific medicine. And there is no help. If the scientific medicine has to be constituted, this is the logical progression of its steps. Beyond this orbit all is empiricism and ignorance, because there does not exist any half science or conjectural science. Following this way the physician has had already the experience of the physicist and chemist, who knew profoundly the existence of natural phenomena, and then modified them, turning them to his profit; the physician has to gauge the stupidity of this sentence, which we hear repeated nowadays, and which he himself often abuses, in the name of badly understood progress, that "Man commands nature."

Now, in reality, the scientific man and also the physician, if he determines to be, and not merely appear, a physician, instead of commanding nature, is to obey her. Let the manufacturers ask themselves who are the legitimate sons of scientific progress; let them ask Franklin, Stephenson, Daguerre, Edison, and other great benefactors of humanity. Yes, it is true they have governed the lightning, they have permitted man almost to annihilate distance, they have given to him the lighthouse of the universe, and controlled the lightning flash, and caused the electric light to rival the sun. But they were worthy and faithful priests of science, and made no pompous promises; they did not discover all the secrets of the phenomena which they undertook to study. If a single link of the long chain of their researches had not been elaborated, no one of you can doubt that the chain would certainly have been broken at the test, and the wonders prematurely announced would have fallen as nothing. Here is what distinguishes inexorably true scientific and experimental progress.

In biology, and especially in the progress of the pathology and therapeutics, this fundamental principle is very often forgotten. And this forgetfulness seems to me to be the true cause which has paralyzed until now the useful results of the immense mass of researches made in the field of medical science.

In experimental science, isolated facts are an idle and dangerous luxury, and in medicine, the isolated and scattered riches cannot produce by themselves useful progress in clinical study. The doctor at the bedside of his patient, after a minute analysis, *needs a synthesis to form a proper opinion, and without synthesis even a most learned doctor is useless to his patient.* In reality, then, we are spectators and authors of really barbarous methods. It amounts to but little that one system be constructed in the name of a hypothesis, and another in the name of a fact; and you will still say it little matters if these systems are called vitalisms, rather than cellular pathology, or bacteriology.

At the present time, medicine unfortunately continues to be the victim of system, and the system of to-day is bacteriology. For those who love sincerely the progress of medicine, it seems to me to be but little charity to hide this dangerous reality, as it would be undoubtedly childish, if not dishonest, to ridicule the great teachings which are included in the discoveries of modern times of a true microörganism continuously at war with man. It is true that in the pages of high genius, like Brieger, Klebs, Sternberg, and others, it is stated distinctly how, for the present, the limit is to be fixed to this new era of pathology and therapy; but the current of mediocrity overwhelms all, conquers the masses, and inspires then absolutely those who now have no science and who are ready to cry "Hail!" to-day to Christ and to-morrow to Mahomet. The only reason which has permitted a systematic invasion most attractive in its domination, of cellular pathology, is the complete forgetfulness of the laws of the experimental method in the progress of medicine. Without pretending to seek the prophets of bacteriology in the poem of Lucrezeio ("De natura rerum") or in the "Contagium animatum" of the Middle Ages, I will only say that the idea of living microscopic germs which insidiously penetrate the human organism by way of the lungs, stomach, and skin, and are capable of developing definite diseases, is not new; it was already presented to the mind of the physician in former times under another name; and it would suffice to remember the universal panacea of camphor, which, more than half a century ago, held in check for a long time a good part of the medical faculty.

But these trials do not deserve any credit for the effective progress of micro-biology, of which the first light is owed, undoubtedly, to Cagniard Latour, who formally announced that if brewer's yeast fermented sugar, this was the same as the generation of life. No one could have believed in those times—1825—that in these words would be included the embryo of one of the most fortunate natural discoveries of the nineteenth century. I do not purpose here to tell you through what rigorous and scientific ways this great discovery has advanced, and what obstacles it had to conquer. I can remember that the memorable researches of Colin and Davaine, in 1851, on the bacteria of carbuncle, and those of Pasteur on the transformation of lactic acid to butyric acid (1861) and on the silkworm disease, have been the starting-point of the scientific modern movement. Researches more memorable, inasmuch as they show that when science walks, without overstepping

herself, on the path of rigorous experience, she will arrive at satisfying and lasting results.

The work of Rüdinger who was the first to presume to scan the vast horizon which opened before scientific medicine in regard to physical and chemical conditions necessary for the development of microbes, should suffice to define in a precise manner the favorable and necessary conditions to the development of the common mould fungus, known under the name of Aspergillus niger. He demonstrated that the slightest trace of nitrate of silver in the proper culture medium would be sufficient to hinder the development of these mould fungi. He should have infused in investigators a great prudence and a great prudence, but for more than ten years pathology instead of advancing with measured and secure steps, pretends to become, itself, pathology. It was a true whirlwind, enveloping all and, at the side of precious discoveries like that of the bacillus of anthrax, of tuberculosis, and some others which are an honor to science, came forth from every part microscopical researches on the existence of new microbes in all diseases, and every sickness seems to have found its true germ, destined, perhaps, to die before being registered. For the past five or six years one could not open a paper without finding registered the discovery of one or more new pathogenic microbes. I have to say that while attention remains so distracted by many problems unsolved in pathology, the easiest way to enter into the path of celebrity has been, and is, the announcement of some new microbe or some new bacillus. Pathology has come to be proclaimed almost the same as bacteriology. Every clinician finds it indispensable to open at the side of his hospital ward a laboratory for bacterial culture. On one side of the hospital is a room for the cultivation of bacteria, and on the other is a room for patients, and the expenses of the first are often greater than the allowance for food for the second.

These discoveries are proclaimed on all sides as the true foundation stone of biology, and doctors hasten with eagerness to proclaim that the only end for cure in sickness is inoculation of microbes, or at least to prepare the organism for surviving the work of the cure by inoculation.

It would be a superfluous work in this place to state the ridiculous childishness which filled the minds of those, who finding it more convenient not to follow the thorny path of the experimental method, attached themselves eagerly to the organ of any new idea, believing that this would be enough to confirm themselves as progressive men. The learned and honest student who has to-day a desire for knowledge would only have to pass in review the strange cures which have been proposed for diseases in the last ten years and note the progress of events, to doubt his own eyes! All these curative propositions were made and are still repeated in the homage of scientific medicine. It is sufficient to recall the trials which were made in many clinics with the most poisonous parasites, to kill the bacilli of tuberculous and consumptives, aggravating, instead, their miserable existence. It is enough to remind you of carbolic acid and salicylate of soda advanced as sure remedies for cholera and yellow fever. On the other hand, one must not be unjust and doubt the honesty of a progressive man because a certain theory has failed to make itself felt among those who put the organism at its greatest disadvantage by applying dangerous preparations of pharmacy, useless according to the teachings of the laboratory, to inoffensive processes. The use of one poison, whether bacillus or drug, to drive out another is irrational and highly injurious, as shown by statistics. Man lives surrounded by microörganisms, over which he triumphs, as he does over the material world.

The biology of the present must solve the problem of man's relation to these microörganisms and the source of their power. Bacteriology has gone beyond its premises, beyond its point of start, and is an unworthy invasion in the field of evolution. I have found the air by analysis full of microbes, but as yet we possess no test as to their being injurious or harmless germs. We cannot ascertain correctly the soil in which microbes grow nor their mode of life, and hence one factor of the problem remains unknown. The claim of Klebs to discriminate between a poisonous germ and a large family of non-poisonous germs seems unproven. Plants are edible in proportion to their cultivation and soil, not differing morphologically from their poisonous fellows; and if an analogous condition holds good with microbes, the reasoning of the bacteriological method is false. In disease where several microbes are present, we cannot discover which is the fatal one. Observers are too ready to assert that diseases following inoculations are produced by the germ; and I appeal to all lovers of truth to determine if possible which diseases are dependent upon inoculation and which are not. Who has seen malaria, or diphtheria, or any disease, in which it was *proven* that the disease depended upon the microbe? Rodents, ruminants, and some other living organisms, show predilection for anthrax; but the carnivora are exempt from many diseases caused by germs. Davaine and Koch failed in some attempts to transfer certain germs from one animal to another. What positive demonstration can they furnish of the causation of disease? Our physical and chemical knowledge of the blood of different animals is so small that we have no means of knowing what animal furnishes a suitable soil for the growth of these microbes. The chemistry of the tissues of an animal is the true basis of judgment of its inoculability or non-inoculability by germs. This, I think, no scientific man will doubt.

I do not see in modern methods of bacteriological research the true experimental method. Diseases are produced by inoculation, but are these morbid processes dependent upon the germ or upon the soil in which it is implanted? Demonstration by this method fails; nothing is positively proven; and in the majority of cases common good sense pronounces against the attempted proof. If this method be correct, physiology must be suppressed or reversed. Suppose a man, when sweating, should enter a cave and remain there several hours, contracting a violent acute rheumatism, do you mean to say that I must seek the cause of his disease in a microbe, or did a profound derangement of the physiological conditions occasion the disease? If I find a few microbes, shall I not consider them the effect and not the cause of the disease? In osteomalacia and endocarditis acuta the relation affirmed to exist between the microbe and the disease has not been proven. This failure illustrates the failure of this method when applied

to the true experimental study of disease. Staphylococcus aureus, when injected into the bloodvessels, will cause general infection, but not osteomalacia purulenta.[1] If, after inoculation, a bone be broken and osteomyelitis purulenta occurs, I ask, in the interest of scientific men, if this occurrence proves the causation of the terrible disease in the helpless animal by the microbe? Endocarditis purulenta is not caused by the injection of microbes; the insertion of a sterilized sound through the carotid artery will cause injury and endocarditis with all its results. So many factors enter into the solution of the problem, that I regret, for experimental medicine, that such hasty observations should be considered of value.

The unknown quantity is too large a factor to be ignored, and any method which disregards it is too much like the utterances of the Delphic Oracle to be considered by thinking scientific men. The true therapeutics will be that science of medicine which shall relieve suffering with the certainty of success. Malignant pustule has occurred when the point of infection is removed; and a similar reasoning is applicable to typhoid fever. In phthisis, the terrible disturbances of nutrition in the patient are the principal factors of the disease, whatever the bacteriologists may say to the contrary; if the patient could rid himself of the bacilli, his life could not be saved. In the absurd miracles chronicled by surgical bacteriologists, the differences between defective antisepsis and curative antisepsis seem to me almost childish. Lister's discovery will doubtless remain an endless source of fame to him, and one of the treasures of the last half of the present century. But Lister's cleanliness closes the doors to poisonous materials which older surgeons had allowed to remain open through their carelessness. It is absurd to quote the success of Lister as an argument for the use of parasiticides. The destruction of microbes outside of the body by antiseptics is no criterion of judgment by which to estimate the success of intracorporeal disinfection. We recognize our inability to prove the entrance of germs by the many avenues open to them, and my long clinical experience leads me to the positive conviction that bacteriology is greatly beyond its reasonable assumptions.

I have shown how bacteriology has exceeded its proper limits, and I now desire to call your attention to its detrimental influence upon pathology. The true part played by bacteria in pathology is the production by them of certain noxious and decomposed elements of the blood, which substances, and not the bacteria, are the potent factors in the causation of disease. The treatment of the physical and chemical constitution and conditions of the blood is a much more fruitful field for study and investigation than a direct attack by germicides upon the bacteria. The human body in health is a laboratory in which are constantly conducted chemical activities of the most complicated nature, and this is doubly true in disease; the action of the pharmacopœia may be best explained by the effect of these substances upon the chemical composition of the elements of the body. The new school of experimenters in therapeutic medicine, among whom Nencki, Husemann, Gussenbauer, Kobert, and Georgi have given especial promise of brilliant results, have investigated sufficiently to refute the reasonings of the purely bacteriological experimenters. The securing of the proper chemical conditions of the body is the object of this school; in other words, to put the organism in harmony with that universe, created by chemical atoms, by which it is surrounded. We are led to follow the counsel of the hygienist, and say, preserve your health, conserve your strength, and disease will affect you but little. Science will show us the particular physical condition of the body which renders us open to the attack and lodgement of a particular microbe.

Hereditary phthisis is well known, as a convenient example of the chemical conditions of the body predisposing to infection by microbes, and the presence or absence of these conditions explains the personal immunity or liability to the disease. The statement that the predisposition to phthisis is not dependent on chemical conditions of the tissues, is the exchange of one ignorance for another. We do not know how to remedy this condition of the tissues which predisposes to the lodgement of the tuberculosis bacillus, except by hygienic strengthening treatment, food, and all exercises which tone, and strengthen, and increase the organism. Unhappily, we cannot ascertain in the laboratory what peculiar changes there are in the tissues which sometimes enable an animal, already attacked by tuberculosis, to endure further infection, and finally conquer the infection. What comparison can there be between the slight changes occurring in an animal deprived, in the laboratory, of fresh air and proper food and care, and the slow, but extensive, changes of tissue which go on in the human being, although apparently the individual is in good health? Physiologically and bacteriologically considered, between these two conditions there is an abyss. Science recognizes this, but has not the means of closer approximating to the truth. The most delicate chemical tests do not demonstrate the intermediate conditions of the organism which have rendered possible the lodgement of a bacillus. What has been said of tuberculosis can also be predicated of all diseases said at the present day to be caused by bacteria. The assertion that a good culture soil is present in those persons who are susceptible to smallpox, scarlatina, and other diseases of their kind, explains nothing.

What are we to say regarding the immunity which the first attack of parasitic diseases causes from a second? The theory that the first attack exhausts the soil favorable for bacteria, we cannot accept, because there is no reason why this material should not speedily reaccumulate after recovery. How are we to explain those cases of scarlatina which recur several times after the first attack in infancy? It is a mystery. How do we explain the fact that one case of scarlatina runs a typical course and recovers, and another case lingers with diseased glands and joints. I admire the ingenuity of bacteriologists, and I bring forward this statement to show in its true light, that their assumptions are not the corner-stone of a new clinical philosophy; but that no matter how germs may grow in broth or in the potato, we know as little from them as before. If you do not accept the chemical changes in the body which constitute a predisposition to tuberculosis, you may bid farewell to scientific conceptions of morbid processes. There can exist no superstructure of medicine, however

[1] Weichselbaum: Klinische Zeit und Streit Frag. Vienna, 1887.

true, however false, upon this foundation. One must remark with Victor Hugo, "I looked for an edifice, and I found a ruin!" In the itch insect we see the result of local irritation in furthering the spread of the mischief. A slight change in general nutrition and hygiene is often sufficient to secure the loss of the insect and the return of the person to health. In what way could these simple changes have influenced the chemistry of the tissues sufficiently to cause a repulse of the parasite? I believe that science should honestly confess its inability to solve these problems. Excepting the better known and stronger substances used in medication, we can say nothing certain regarding scientific therapeutics at the present day; and medical science is content to remain satisfied with the little which is known about the substances mentioned. The advance-guard of science represents the fly upon the oxen's back urging his huge leaders to plow.

The dictum of modern therapeutics is, that remedies are given to destroy germs; but by the same reasoning mercury is given for syphilis and quinine for malarial fevers, while the direct existence of disease germs has not been proven in either case. The assertions of the modern school are proof of the injurious domination of a mistaken idea, and adherents of these theories imagine that they see in the patient the germs which they behold on looking through the microscope. The fact that solutions of bichloride of mercury in strengths of 1 to 1000 and 1 to 4000 are efficient germicides, proves nothing regarding their effect upon the germ of syphilis, for the following reasons: It is commonly thought that bichloride of mercury combines with the albumen of the tissues and their sodium salts, to form combined albuminates of mercury; and that these compounds act upon the albumen in the syphilitic germ, which is impossible when the mercury has exhausted its combining powers in its first combination. To avoid these contradictions pharmacologists form a hypothesis. If we admit that mercury kills syphilitic microbes, it does so in a solution of 1 to 5000. To combat successfully the germs of syphilis it would be necessary, by calculation of body-weight, to give a patient fifteen grains of bichloride of mercury, an amount, I need not say, which would be fatal in its results. Following this calculation, it would also be necessary to give at least sixty or eighty hypodermatic injections daily in the treatment of syphilis, representing in all from five to six grains of the bichloride of mercury. If we remember that after the third or fourth injection, traces of albuminates of mercury are found in the urine, we shall see that the whole amount necessary to complete the natural cure must be very great. Following the same reasoning, why should not mercuric chloride cure tuberculosis? There is no necessity for reviving a theory followed with such sad results. Empiricism has no place in the temple of medical science—it is a dead issue.

The true experimental philosophy, seeking the causes and acting from truth thus derived, has made its healthful influence felt not only in medicine but in social science. To you Americans the experimental method is that not only of science, but of your government and its institutions. With empirical anarchy you have nothing in common. The great facts of clinical observation transmitted through centuries, are the precious basis of modern medical science. It is the duty of the physician, at present, to apply to these great stores of knowledge the clear light of the chemistry and physics of the present; its anatomy, pathology, and physiology, and thus to deduce rules of action for the investigation of new facts and new truths which arise in the clinical observations of to-day. In such a manner only can we hope worthily to contribute through an extended period of time, to the solid structure of truly scientific medicine.

Let use see to it that we adhere rigorously to the sound principles of correct observation, that we may avoid the errors of past ages and not stray from our onward path through the false light of erroneous hypothesis or extravagant generalization. Thought should be national in its true freedom and catholicity. Science knows no fatherland, and as long as it is fearless to conquer, will enlist under its banner the peoples of the earth. Each nation contributes characteristic studies to the accomplishment of the whole. To nations who look back to grand traditions, the remarks of Virchow, at the Congress of Naturalists at Hanover, in 1886, are particularly appropriate: "Science is unproductive when it has no national character," and that "Germany herself says that this scientific progress consists only in following her example—imitate no one if you wish to revive your science and reach your former grandeur." From no other corner of the earth could my humble voice reëcho more powerfully the history of my fatherland's experimental medical science than from America. Let us follow faithfully the banner of science, taking for our motto that message which the physician of the Egyptian army sent to Napoleon, "It is my duty to conserve and not to destroy."

MEDICAL PROGRESS.

A NEW COLORING MATTER IN URINE.—LEUBE reports that he has found a coloring matter in the urine of those suffering from osteomalacia, cystitis, and nephritis, which turns on exposure to the air from dark violet to black. This amorphous substance dissolves in ether; it is separated by dilute alkalies, not by acid; the alkaline solutions are at first reddish-brown and afterward yellow. This coloring matter is soluble in hot water, chloroform, and benzol. The alcoholic solution is decolorized by zinc, but assumes its color on exposure to the air. The solutions show characteristic spectra or flourescence.—*Fortschritte der Medicin*, July 15, 1887.

PERITONITIS PRODUCED BY FOREIGN BODIES.—PERNICE has made experiments by injecting small quantities of concentrated mineral acids, acetic acid, carbolic acid, a concentrated solution of bichloride of mercury, and nitrate of silver into the abdominal cavities of puppies and young pigs; peritonitis followed, and sometimes necrosis and intestinal perforation. The peritonitis was serous or sero-fibrinous, without suppuration. In the exudate was a form of micrococcus, generally diplococcus or chain bacterium, which liquified gelatine. These bacteria probably come from the blood of the animals, for they were found in the blood of healthy animals, and abundantly in the air of the laboratory and stalls where the animals were confined. Pure cultures of these bacteria produced no peritonitis.—*Centralblatt für klinische Medicin*, July 16, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE. . . . . $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 10, 1887.

THE INTERNATIONAL MEDICAL CONGRESS.

As will be seen from our Washington dispatches, the Ninth International Medical Congress was duly opened in accordance with the announced programme, and is in the midst of its sessions as we write. It has been favored with almost perfect weather, and its members have had the opportunity of seeing one of our most beautiful cities under exceptionally favorable conditions of sky and air.

A part of the work of the Local Committee of Arrangements has been well done, the rooms provided for the different Sections were sufficient and well located, and the arrangements for registration were satisfactory, except for a few hours during the greatest rush. The part relating to entertainments, we regret to say, however, was not so satisfactory, as may be inferred from the statement of the Chairman of the Committee to the Congress on Wednesday morning, in which he referred to "the humiliating spectacle of Monday night," and spoke of the foreign guests as having been "engulfed in a mob at the President's," both of which expressions were more than justified by what occurred.

On the other hand, it is with great pleasure that we call attention to the admirable manner in which the Secretary-General has performed the onerous and difficult duties of his office. To the signal executive ability and unwearying zeal of Surgeon-General Hamilton is due, in a large degree, the measure of success which the Congress has attained.

Great complaint has been made by the Local Committee and others, as to the insufficiency of funds for social entertainments, excursions, etc., and this deficiency has been, with questionable justness, attributed to the parsimony of Congress, which has been freely denounced in consequence. The fact is, however, that at only two of the preceding Congresses has any grant of money been made by the Government of the country in which the meeting was held, and the largest of these grants—*i. e.*, that made by Denmark—was precisely that given by Congress, viz., $10,000. Municipalities have in three cases voted funds for entertainments, but the chief source of supply has always been private contributions, as it should be. Certainly, in the beginning, no governmental aid was expected, and it was so stated at Copenhagen, when the invitation was presented to the Executive Committee of the last Congress. The complaints referred to are in very bad taste, and can in no way excuse the mismanagement of the social features of the Congress.

The number of persons actually present is upward of 2500, and of these about 130 are from abroad. A number of the foreign members were registered by mail, and were not in attendance. The election as vice-presidents of a number of foreign gentlemen who were known not to be present, or even registered, was in opposition to all precedent, and was not a wise or dignified proceeding.

As to the character of the work done, the amount of new and valuable information which has been presented, and the probable influence which these will have on the science and art of medicine in the future, it is perhaps too soon to venture comment or prediction, but the opinions expressed by a few prominent men, which we print elsewhere, are interesting in this regard. The preliminary programme announced about five hundred papers as having been promised. Quite a number of these were not on hand when called for, but there were many others offered which were not on the programme, and it is safe to say that each member of the Congress will be entitled to receive several very bulky volumes in the shape of its transactions, and that the editors of these volumes are not to be envied.

The American profession has desired to extend a most cordial welcome to the foreign members who honored us by their presence at Washington, and it is a source of gratification to find that so many of our guests have shown their appreciation of this sentiment by bringing with them scientific contributions which cannot fail to add materially to the merits of the Congress as an educational gathering.

A feature of the Congress has been the attention given to it by the daily press, and the likenesses given in the Washington papers of men whom they consider specially worthy of honor form a collection which is unique in medical portraiture.

We evince our own interest in the Congress by devoting this entire number, which contains sixteen extra pages, to the report of its proceedings.

PROFESSOR FLINT'S ADDRESS.

IN the choice of the subject of Fever, upon which to address the Congress, Dr. Flint was peculiarly happy, as he not only had an opportunity of discussing a scientific problem of the deepest interest, but he was also able to deal in a very practical manner with principles of treatment of everyday importance to the practitioner.

The theory of fever advanced by Dr. Flint has, in certain respects, the merit and attraction of novelty. He would define fever, as observed in the so-called specific diseases, as a condition of excessive formation of heat, involving defective nutrition, an excessive production and discharge of nitrogenous matters, with wasting of the tissues and *partial or complete suppression of the production and discharge of water*. This latter proposition forms the central point in his theory. Physiological considerations, which are dealt with at length, indicate that water is formed in the body by the union of oxygen and hydrogen, and is often discharged in excess of the water of food and drink. This water is a product of oxidation, an excretion which may be compared with urea and carbonic acid, and its formation is closely connected with the process of calorification. In health this production of water with the generation of heat "seems to carry with it the conditions for equalization of the animal temperature by cutaneous transpiration." In simple inanition and in excessive muscular exertion there is an increased discharge of water, the formation of which economizes the tissues of the body, and in these conditions, were it not for this increased formation of water and the cutaneous transpiration, the temperature of the body would be raised. In pyrexia with an increase in the discharge of carbonic acid and urea, there is a diminished formation and excretion of water, and it is the suppression or reduction of these important processes which allows the rise in temperature.

Dr. Flint's views on the rational treatment of fever follow naturally, and are based upon the physiological considerations. Clinicians will read with great interest his remarks on the value of alcohol as a food in fever. It presents a form of hydrocarbon which is readily absorbed and promptly oxidized, and saves destruction and degeneration of tissue. And as in its oxidation water is formed, its action in fever thus "tends to restore the normal processes of heat production, in which the formation of water plays an important part."

The question of fever presents many difficulties, and before we can expect a full and clear explanation of its pathology, we must know more of the laws regulating the formation and discharge of heat in health. The views here announced are valuable as based on careful physiological observations, and though some of the conclusions will excite opposition and may be open to criticism, there can be no doubt that Dr. Flint has given us a most suggestive contribution to this complicated subject.

THE HYPODERMATIC USE OF ERGOTIN.

IN hemorrhage inaccessible to mechanical means of arrest, the hypodermatic use of some form of ergot has proved one of the most successful of therapeutic expedients. In puerperal hemorrhage the abdominal wall was chosen as the place of injection, and the fluid extract of ergot and various preparations of ergotin have been employed. This mode of treatment, however, is not without unpleasant results in an irritative effect of the drug, producing pain, and often abscesses.

To avoid these objectionable features, BUMM, in an article in the *Centralblatt für Gynäkologie*, No. 28, 1887, strongly urges the selection of the nates as the place of injection; the needle of the hypodermatic syringe should be inserted perpendicularly in the gluteal muscles for its entire length. The muscular tissue is shown to be less sensitive and more efficient as an absorbent than the subcutaneous tissue; experiments upon animals show that twelve hours after such injections all traces of the fluid disappear, while portions of material injected into the abdominal wall remain for more than twenty-four hours.

A second point of importance is the choice of an appropriate preparation of ergot. Bumm believes that the strongly acid reaction of the extracts and their solutions is an important factor in the production of the burning pain so often caused by injections. The suggestion of other writers, that the power of the drug is impaired by neutralization of its solution, Bumm did not find verified in the cases of two patients whom he treated for uterine fibroids, using in alternation acid and neutral solutions. The addition of soda to full neutralization gave a clear fluid which was perfectly efficient.

The use of too concentrated solutions is another cause of irritation. Ordinarily one part of ergotin to five of water is recommended, but much more rational is the selection of a five or ten per cent. watery solution. A better result is obtained from a larger quantity of a weaker solution, both as regards rapidity of absorption and continued action, than from a smaller quantity of a stronger solution. A slight sensation of burning, or tenderness on pressure, are the only unpleasant after-effects which Bumm has seen to persist, and for a few hours only, after this treatment.

THE Crown Prince of Germany has written to Professor Virchow, announcing a continued improvement in the condition of his throat, and thanking the renowned pathologist for his investigations

into the character of his Imperial Highness's malady.

It is reported that the Queen has intimated her intention of conferring the honor of knighthood upon Dr. Morell Mackenzie in recognition of his professional services to the Crown Prince.

THE American Gynecological Society will hold its annual meeting at the hall of the Academy of Medicine, in New York, on Thursday, Friday, and Saturday, of next week. Dr. A. J. C. Skene, of Brooklyn, is the President for the year.

At the meeting of the American Dermatological Society, held at Baltimore, last week, Dr. I. E. Atkinson, of Baltimore, was elected President for the ensuing year.

ACCORDING to a press cablegram there were reported last Tuesday 6 new cases of cholera and 2 deaths in Rome, 13 new cases and 10 deaths in Palermo, and 27 new cases and 18 deaths in Catania.

AN epidemic of scarlet fever is now prevailing in London. The fever hospitals are reported to be full of patients, and up to September 7th, 1120 cases had been reported to the health authorities.

SOCIETY PROCEEDINGS.

NINTH INTERNATIONAL MEDICAL CONGRESS.

Held at Washington, September 5–10, 1887.

(Specially reported for THE MEDICAL NEWS.)

MONDAY, SEPTEMBER 5TH.

GENERAL SESSION.

THE Congress was called to order promptly at 11 o'clock, by the Chairman of the Executive Committee, HENRY H. SMITH, M.D., of Philadelphia. He said it was known to all present, as well as to physicians throughout the world, that in May, 1884, representative members of the profession in the United States decided to send a fraternal greeting to the Eighth International Medical Congress, then about to assemble in the capital of Denmark, and ask that the Ninth International Medical Congress might meet in the city of Washington. This invitation being accepted, an executive committee was named to make the necessary arrangements, and the result of their labors was seen in this large assembly, which the register showed contained many of the most brilliant and distinguished medical minds of Europe, Asia, and America. To welcome these guests of the profession, and show his interest in a great humanitarian object, the President of the United States had consented to open the Congress for organization.

The President arose, and when the applause had subsided, he said:

"I feel that the country should be congratulated today upon the presence at our capital of so many of our own citizens and those representing foreign countries who have distinguished themselves in the science of medicine and are devoted to its further progress. My duty on this occasion is a very pleasing and a very brief one. It is simply to declare that the Ninth International Medical Congress is now open for organization and for the transaction of business."

ELECTION OF OFFICERS.

The Chairman of the Executive Committee then nominated Dr. N. S. Davis, of Chicago, for President of the Congress, and he was elected by acclamation, and Dr. Francesca Durante, of Italy, and Deputy Surgeon-General Jeffry A. Marston, of the British Army, were appointed a committee to escort him to the chair.

Dr. J. B. Hamilton, Supervising Surgeon-General of the United States Marine Hospital Service, having been nominated and unanimously elected Secretary-General of the Congress, took his place and nominated the following gentlemen as

VICE-PRESIDENTS OF THE CONGRESS.

United States.—Surgeon-General Moore, U. S. A.; Surgeon-General Gunnell, U. S. N. (ex-officio); Dr. William Brodie, Detroit; Dr. W. W. Dawson, Cincinnati; Dr. A. Y. P. Garnett, Washington; Dr. Edward M. Moore, Rochester; Dr. Tobias G. Richardson, New Orleans; Dr. Lewis A. Sayre, New York; Dr. Joseph R. Smith, New York; Dr. J. M. Toner, Washington.

London.—Dr. Cuthbert H. G. Bird; Dr. A. Pearce Gould; Mr. Ernest Hart; Dr. Jonathan Hutchinson; Sir James A. Hanbury; Sir William Jenner; Dr. Fred B. Jessett; Dr. William H. Lloyd; Dr. William Murrell; Dr. Jeffrey A. Marston; Mr. Thomas J. MacLagan; Dr. John Marshall; Dr. Morrell Mackenzie; Dr. William A. MacKinnon; Dr. Charles D. F. Phillips; Mr. Richard Quain; Sir John W. Reed, K. C. B.; Mr. William H. Savory; Sir Edward H. Sieveking; Dr. John Tweedy; Sir Henry Thompson; Sir William W. Gull.

England.—Dr. J. Ewart, Brighton; Sir B. Walter Foster, Birmingham; Sir Thomas Longmore, Netley; Dr. John D. MacDonald, Surrey; Dr. Withers Moore, Brighton; Sir William Roberts, Manchester; Dr. John B. Sanderson, Oxford; Mr. Lawson Tait, F.R.C.S., Birmingham; Sir John Tomes, Surrey; Dr. George M. Humphrey, Cambridge.

Scotland.—Dr. McCall Anderson, Glasgow; Dr. Thomas Annandale, Edinburgh; Dr. John Chiene, Edinburgh; Dr. T. R. Fraser, Edinburgh; Sir Douglas Maclagan, Edinburgh; Dr. George H. B. Macleod, Glasgow; Sir William Turner, Edinburgh.

Germany.—Dr. William Koch, Berlin; Dr. Frederick Esmarch, Kiel; Dr. A. L. Gusserow, Berlin; Dr. W. D. Müller, Berlin; Dr. Carl von Mosengsill, Bonn; Dr. G. Unna, Hamburg; Dr. Waldeyer, Berlin; Prof. E. Winckel, Munich.

France.—Dr. Dujardin-Beaumetz, Paris; Prof. A. Charpentier, Paris; Dr. A. Chervin, Paris; Dr. Vallin, Paris; Prof. Trelat, Paris; Dr. Léon Le Fort, Paris.

Austria.—Prof. Carl Braun, Vienna; Dr. Ehrendorfer, Vienna; Dr. Hans R. von Hebra, Vienna.

Switzerland.—Dr. F. Dumont, Berne; Dr. Theodore Kocher, Berne.

Italy.—Dr. Francesco Durante, Rome; Dr. O. Morisani, Naples; Dr. Mariano Semmola, Naples.

Egypt.—Dr. A. S. Grant-Bey, Cairo.

Halifax.—Dr. Thomas M. Dolan.
Ottawa.—Dr. J. A. Grant.
Havana.—Dr. Nicholas Jose Gutierrez.
Copenhagen.—Dr. Wilhelm Meyer.
Honolulu.—Dr. John S. McGrew.
Belgium.—Dr. Leopold Servais, Antwerp.
Dublin.—Sir William Stokes.
East Indies.—Dr. George J. H. Evatt.
Hague.—Dr. J. E. de Virij.

The President of the Congress put the question, and the gentlemen named were elected by acclamation.

A Delegate.—Mr. President, I would like to ask, sir, if it is proper to elect as Vice-Presidents those who are not members of the Congress. I protest, and move to amend—

President Davis.—It is hardly proper to interrupt the proceedings now. It was impossible to know who would be here in person. Gentlemen named were notified, and all accepted the places. The list as read is elected, and I have the honor to invite the Vice-Presidents to seats on the stage.

The following gentlemen were then elected

PRESIDENTS OF SECTIONS.

General Medicine, A. B. Arnold, M.D.
General Surgery, W. T. Briggs, M.D.
Military and Naval Surgery, Henry H. Smith, M.D.
Obstetrics, DeLaskie Miller, M.D.
Gynecology, Henry O. Marcy, M.D.
Therapeutics and Materia Medica, Traill Green, M.D.
Anatomy, W. H. Pancoast, M.D.
Physiology, J. H. Callender, M.D.
Pathology, A. B. Palmer, M.D.
Diseases of Children, J. Lewis Smith, M.D.
Ophthalmology, J. J. Chisolm, M.D.
Otology, S. J. Jones, M.D.
Laryngology, W. H. Daly, M.D.
Dermatology and Syphilography, A. R. Robinson, M.D.
Public and International Hygiene, Joseph Jones, M.D.
Climatology and Dermatology, Albert L. Gihon, M.D.
Psychological Medicine and Diseases of the Nervous System, J. B. Andrews, M.D.
Dental and Oral Surgery, Jonathan Taft, M.D., D.D.S.

The Congress then confirmed the selection of the remaining officers of the Congress.

THE REPORT OF THE SECRETARY-GENERAL

was then read by Surgeon-General Hamilton. According to the practice at former associations of this body, the Secretary must make a report of the work performed since the session of the Congress last preceding. In doing this it was his aim to occupy as little time as possible.

He said it was now a matter of history that in May, 1884, the American Medical Association met in this capital and passed a resolution inviting the Congress to honor America by holding its next session in the United States. At the meeting in Copenhagen, when the question came up for disposition, Washington was selected. The committee, having borne the invitation and secured its acceptance, returned home and immediately began the work of organization. Shortly before the meeting of the American Medical Association in New Orleans in May, 1885, the preliminary organization was completed. But it transpired that this committee was unable to form an organization satisfactory to the majority of the members of the Association, and after some discussion a resolution was adopted which authorized the appointment of additional members of the committee so as to include, in accordance with our American system of representation, one member from each State and Territory, and to these were added one representative from the Army, the Navy, and the Marine Hospital Corps. The enlarged committee met in Chicago, and a majority of the first committee was present and acted harmoniously with the new committee. In a short time, however, the members of the original committee withdrew and the management was thus deprived of their valued services. The committee had to contend against more than the ordinary difficulties attending so great an undertaking. The time was too short to speak adequately of the multifarious labors attached to the office of the Secretary-General, but he had to report that at the present moment there remained no unfinished business on the Secretary's table. The work of organization was now complete, and he submitted the programme and the volume of abstracts.

In regard to the programme, he stated that the rule requiring titles and abstracts of papers to be read to be in the hands of the Secretary-General before the 30th of April, had not in a single instance been complied with. Owing to this delay, the work of publication had been done in a hasty manner, and of necessity at the expense of many errors.

The contract for printing the volumes of *Transactions* has been let, and the work will be done with as much dispatch as possible.

Dr. A. Y. P. Garnett, of Washington, Chairman of the Committe of Arrangements, then announced

THE SOCIAL PROGRAMME

of the Congress.

Monday evening, there would be a conversazione at the United State Pension Building.

On Tuesday, the President of the United States will hold an informal reception at the Executive Mansion, from 8 to 9 P.M., after which the members will proceed to visit the Corcoran Art Gallery.

On Wednesday afternoon, from 4 to 6, the Hon. Josiah Dent will give a lawn party, to be attended only by those who receive cards of invitation.

On Thursday there will be a reception and banquet at the United States Pension Building, from 8 to 11, at which it is hoped that the President of the United States and his Cabinet will be present.

On Friday, the Secretary of the Navy, Mr. Whitney, will give a reception at Grass Lands, his country residence.

On Saturday, there will be an excursion to Mount Vernon for the foreign members and their families only, the United States steamer "Dispatch" having been kindly granted by the Secretary of the Navy for this purpose. In the afternoon, an excursion train will start for Niagara Falls and Watkin's Glen, also for the foreign members and their families, who will be conveyed free of charge. American members may also attend at the excursion rate.

In conclusion, Dr. Garnett remarked that it was a

source of profound regret and embarrassment to the Committee that the month of September had been chosen as the time of meeting, and it was their painful duty to explain to the visiting members that they had come to a city literally and almost entirely deserted of its inhabitants, who were thus prevented from displaying the hospitality for which they are justly noted.

THE SECRETARY OF STATE'S ADDRESS OF WELCOME.

THE PRESIDENT, DR. DAVIS, then introduced to the Congress the Hon. Thomas F. Bayard, Secretary of State, who welcomed the Congress in the following address:

"*Gentlemen of the International Medical Congress:* The pleasing duty has been assigned to me of giving expression, in the name of my fellow-countrymen, to the gratification felt by us all that you should have selected this Capital to be the scene of your Ninth Congress, and cordially to bid you welcome.

"The world is becoming better acquainted, social assimilation has progressed, small provinces and minor kingdoms are federalizing into great empires, international intimacy suffers less obstruction, the broad and powerful current of literature is silently wearing away the banks of geographical prejudice, and a spirit of a common brotherhood, of mutuality and independence is expanding itself irresistibly over the barriers of mountain and sea, and these new and beneficent conditions give promise that the word 'stranger' shall soon be obliterated from the vocabulary of civilization.

"You gentlemen will not, I hope, feel—and I am sure you will not be considered by us—as strangers in the United States; for not only has the fame of many of your number—whom to name might seem invidious—long since surpassed the limits of your own lands and been recorded in the world's annals of scientific attainment, but I take leave to say that here especially will your claims for public respect and grateful acknowledgment due to your enlightened services find prompt and hearty allowance by the populations who dwell amid the blessings of civil and religious liberty beneath the broad banner of these United States.

"If letters be a republic, science is surely a democracy, whose domain is penetrated and traversed by no royal road, but is open on all sides and equally to all, who with humility and intelligence shall watch and wait for light as it is gradually disclosed by divine Providence for the amelioration of mankind.

"In this democratic republic the brotherhood of science can best realize its universality; for here you will find institutions for the promotion of science in every department—and in none more conspicuously than in that of medicine and surgery—the most important of which are the voluntary gifts of private citizens, men who, in the great majority of cases, were painfully limited in their associations with science and letters, who began life at the lowest round of fortune's ladder; but, thanks to the noble equities of our political system, rose without 'invidious bar' to the highest level of material success and public usefulness.

"To the public spirit and benevolence of such individuals is due the endowment, on a scale that princes may envy, but have never surpassed, of schools of science, colleges, and universities, open for the intellectual training and advancement of all who desire to share and are competent to receive such benefits.

"Your Congress is held, gentlemen, in the year of the first century of our national existence, and what has been here accomplished in the line of scientific education and equipment owes comparatively little to official or governmental assistance. To no system of prescriptive privilege, but to individual energy, enterprise, and generosity, we owe what, under God, we now possess of such things, and non-interference by the Government has proved a promotion and not a hindrance in our advancement. Busy in every department of industrial pursuit, engrossed with diversified occupations, and hurrying with a breathless energy that has left its traces upon the physiognomy of our people, yet, believe me, we are not deaf to the calls of humanity nor lacking in appreciation and grateful respect for the votaries of science.

"We welcome this Congress as guardians of the sanitations of the nations. In your profession we recognize the noblest school of human usefulness, and in the progress of the development of the laws of cure, the mitigation of suffering, the prolongation of human existence, and the efforts to discover the true principles of conditions by which life can be made 'worth living,' we have learned to appreciate our debt to those whose highest reward is the 'still small voice of gratitude' and consciousness of benefaction to the human race. Gentlemen, I confidently promise your convention a worthy audience—not alone the members of your profession here assembled nor the limited number whom this building can contain—but that vaster audience to whom, upon the wings of electrical force, your message will be daily borne far and wide to the listening ear of more than sixty millions of American citizens.

"Sure am I that your message will be worthy and equally that your thoughtful deliverances will be welcomed by a continent.

"The close relations of mankind which modern invention has induced has been necessarily accompanied by an increased dissemination of disease and the need is obvious of frequent international conference, that in the grand sweep of scientific observation new discoveries in the healing art may be promptly tested and applied in counteraction.

"Forgive me if, as one of the great army of patients, I humbly petition the profession that in your deliberations Nature may be allowed a hearing when remedies are proposed; that her *vis medicatrix* may not be omitted in computing the forces of cure, and that Science may be restricted as often as possible to sounding the alarm for nature to hasten, as she surely will, if permitted, to the defence of the point assailed.

"My duty is very simple, and I fear I have already overstepped its limit, for there was indeed little more for me to say than to repeat the words of an ancient dame whose cottage was close by the battlefield of Waterloo, and, being somewhat deaf, and hearing the sound of the artillery when the famous 'pounding' was hardest, thought she heard some one knocking at her door, and simply said: 'Come in.' This may seem an unscientific illustration of auscultation and percussion, but you need not make half the noise of Wellington or Bonaparte, and I can assure you the American

people will hear you and heartily say to you, as I do for them, 'Come in.'"

RESPONSES BY FOREIGN DELEGATES.

Inspector-General WILLIAM H. LLOYD, R. N., returned thanks on behalf the medical profession of Great Britain and Ireland, as represented by his professional brethren present, for the warm and eloquent welcome to which they had listened from the Secretary of State. He expressed thanks and appreciation of the kind and cordial welcome received from the Congress, and for the honor conferred by the presence and approval of the high officers of State of this truly great country.

DR. LEON LE FORT, of Paris, said he appeared in the name of his countrymen to express their thanks for this welcome. They had crossed the Atlantic to bring to their American colleagues an expression of their sympathy. The reception accorded had already proven that the sympathy was reciprocated. In designating Washington for the Congress the medical profession of Europe desired to affirm the high esteem in which American physicians are held.

DR. P. G. UNNA, of Hamburg, returned thanks on behalf of his German colleagues for the very friendly words with which they had been welcomed. The German physicians who had come to the United States had been most handsomely received. Not only had they found in all parts of the country men educated in German colleges in all the branches of medical science, but they had learned with pride that here German science was appreciated, and that here it had gathered a rich harvest. He begged to convey the assurance that the German members of the Congress would do their best to make the meeting a success.

SENATOR M. SEMMOLA, of Naples, said he was happy to have the honor of replying in the name of Italy and of bringing the salutation of his young and great nation, which regards with profound interest the marvellous growth of this edifice of independence—the United States. He believed international congresses to be among the best means of binding peoples together in liberty, equality, and fraternity, and he flattered himself that this Congress would be a striking example of the invincible power of humanity, marching—science and liberty allied—toward that condition of social peace which was inspired in the United States and would always be a shining mirror of the patriotism of this great people.

DR. CHAS. REYHER, of St. Petersburg, said he would hardly dare to speak were it not made his duty to do so. He would not be understood if he spoke in Russian, and his familiarity with English was very limited. He and all who came with him expected to see and learn much, but they had seen and learned far more than they had hoped. He expressed his hearty thanks for the welcome.

Dr. N. S. DAVIS then delivered

THE PRESIDENTIAL ADDRESS.

Gentlemen and members of this Congress: It is my first duty on this occasion to remind you that death has removed from among us one to whom, more than to any other, we are indebted for the privilege of having the Ninth International Medical Congress in America, one whose urbanity, erudition, valuable contributions to medical literature, and eminence as a teacher caused him not only to be universally regarded the most influential leader in all the preparatory works, but also the one unanimously designated to preside over your deliberations on this occasion. That one was the late Professor Austin Flint, of New York, who was taken suddenly from his earthly labors early in 1886, before the preparations for this Congress had been half completed.

The true nobility of his private and professional character, his ability as a teacher, and the number and value of his contributions to the art and science of medicine had caused him to be known and esteemed in all countries. And, as you well remember, that, while the shock of his death was fresh upon us, his loss seemed well-nigh irreparable. But, though he has taken his departure, ripe in years and full of honors, yet the influence of his excellent example and of his contributions to medical science remain, and will continue to exert a beneficent influence through all the generations to come.

With a full consciousness of my own deficiencies, and still with a heart overflowing with gratitude, I thank you for the honor you have bestowed in selecting me to preside over this great and learned assembly. It is an honor that I appreciate as second to no other of a temporal nature because it has been bestowed, neither by conquest nor hereditary influence, nor yet by partisan strife, but by the free expression of your own choice.

Addressing myself now more directly to those here assembled, who have left homes and loved ones in other lands and encountered the fatigue and danger of travelling by sea and by land, in the name of the Medical Profession of this country I welcome you, not only to this beautiful city and the hospitality of its citizens, as has been so admirably done already by the honorable representative of the Government, who has just taken his seat, but I cordially welcome you to the open arms and warm hearts of the medical men of this *whole country*, in whose name you were invited here three years since, and whose representatives are now here, side by side with you, gathered from the East, the West, the North, the South, as well as from the rugged mountains and fertile valleys of the Centre, to make good the promise implied by that invitation.

If they do not cause you to feel at home and happy, not only in the social circles and halls devoted to the advancement of science, literature, and art in this city of our Nation's pride, but wherever you may choose to roam, from the rocky coast of New England on the Atlantic to the Golden Gate of the Pacific, it will be from no want of earnest disposition to do so.

He then urged that no other one influence operative in human society during the present century has done as much to develop and diffuse medical knowledge, to stimulate its practical and successful application, both in sanitary measures for preventing disease and in the direct alleviation of suffering at the bedside, and in unifying and ennobling the profession itself, as has been accomplished by the aggregate medical society organizations of the world. Yet their capacity for conferring other and perhaps still greater benefits, under proper management, will have become manifest in the near future. And that he might accomplish the chief object of this address, he asked indulgence while he indicated some of the more important additional benefits in ad-

vancing medical science and saving human life through the instrumentality of our medical society organizations, and the methods by which they may be accomplished.

These latter, briefly stated, consisted in the addition to every permanent general medical society, of two standing committees; one, to which should be referred for critical examination every communication claiming to embody a new discovery in either the Science or Art of Medicine; and the other should be charged with the work of devising such lines of investigation for developing additional knowledge as require the coöperation of different individuals, and perhaps societies, and of superintending their efficient execution until crowned with success.

It has been tersely and correctly stated that associated action constitutes the characteristic and predominating power of the age in which we live. It is by associated action that education in its broadest sense, religion, and civilization have been more rapidly diffused among the masses of mankind during the present century, than during any other period of the world's history. It is by the association of capital, wielded by the associated intellects of the nineteenth century, that the highways of commerce have been opened over the valleys, through the mountains, across the deserts, and on the oceans, over some of which the material productions of the nations are borne by the resistless power of steam, and along others the products of mental action are moved with the speed of electric currents, until both time and space are so far nullified that the most distant nations have become neighbors, and the inhabitants hold daily converse with each other from opposite sides of the globe. Indeed, it is only by means of such of these highways as have been constructed within the memory of him who addresses you, that you have been gathered in this hall from the four quarters of the earth, and through which an account of your doings may be daily transmitted to your most distant homes.

In concluding he said, I congratulate you on the fact that the profession you represent has taken the lead of all other professions or classes of men, in rendering available these grand material achievements of the age for cultivating fraternal relations, developing and interchanging knowledge, and planning concerted action for rendering human life everywhere healthier, happier, and of longer duration.

This is the ninth grand International Congress in regular series within little more than two decades, and let us hope that all its work will not only be done in harmony and good order, but with such results as will add much to the aggregate of human happiness through all the coming generations.

Without trespassing further on your patience, I must ask your forbearance with my own imperfect qualifications, and your generous assistance in the discharge of the responsible duties you have devolved upon me.

The Congress then adjourned to meet in Sections at 3 P. M.

SECTIONS.

General Medicine.

The Section was called to order at three o'clock in the Congregational Church, by THE PRESIDENT, A. B. ARNOLD, M.D., of Baltimore, who, after briefly announcing the method to be pursued in the working of the Section, said that the occasion which afforded him the privilege of addressing the representative men of our profession seems not inappropriate to cast a retrospective glance at the methods which exert a dominant influence on the medical practice of the present day. An inquiry concerning the extent and the value of our therapeutical resources under changing circumstances, even if very imperfectly carried out, will not be deemed wholly uninteresting to the reflecting physician. He then referred to the lack of confidence displayed by some on the one hand in the reception of advanced methods of investigation or treatment, and the too hurried adoption of them by others. Candid and competent criticism is evidently the only safeguard against the overweening confidence in favor of therapeutical measures, as well as the best corrective of irrational scepticism.

Although we would naturally expect unanimity of opinion in regard to the treatment of febrile affections which are self-limited, or, at least, display a tendency toward recovery: yet he thought he did not exaggerate when he asserted that there is an English, a French, a German, an Italian, a Spanish, and an American method of treating fever. It may be safely said, however, that the rate of mortality of fever has steadily diminished during the last four decades.

The therapeutics of typhoid fever was then made the topic of special consideration. Although the most beneficial results have been reported from the artificial depression of the accelerated pulse and respiration, yet the essayist did not think the methods have been demonstrated as curative in their results. Hyperpyrexia is an unquestioned danger in fever, and the methods for overcoming it were briefly reviewed by the essayist. We are now more than at any previous time able to meet the causal indications of the disease in our treatment, and we know at the same time more of the method in which our therapeutic measures attain their effects. Hydrotherapy, for example, has its effect through the vasomotor nerves. Nature often cures disease, and a knowledge of her methods of so doing enables us the more scientifically to supplement her efforts in that direction.

In conclusion, he remarked that it is hardly conceivable that medical science will ever attain that degree of perfection which would render it competent to formulate a system of practice that would leave little to the discretion of the physician. A certain independence of action will always be unconsciously exercised. Medical talent in the hands of the brightest ornaments of the profession often assumes a character akin to the inspiration of genius. The display of diagnostic acumen, the mastery of difficulties and perplexities, and the promptness of decision in the presence of urgent realities, constitute accomplishments and performances which rival the brilliant achievements of co-workers in other branches of our profession.

DR. YGNACIO ALVARADO, of Mexico, then read a paper entitled

SOME SUGGESTIONS ON THE PATHOGENESIS OF YELLOW FEVER.

It would appear, he said, pretty well established that the symptoms of yellow fever are due to the presence and action of microbes. It is also a striking fact not altogether new, that there is a strong analogy existing

between the symptoms of this disease and those produced by lactic acid poisoning, on the one hand, and phosphoric acid on the other. To determine the reality of the poisoning by these agents in this disease is extremely difficult, and would require an extraordinary degree of knowledge and skill in chemical manipulations. Assuming, however, that the microbe to whose action is due the manifestations of the disease, by its action on the sugar which it finds in the blood, and more especially in the liver, produces a lactic acid fermentation, that this lactic acid, combining with the phosphate of soda in the organism, occasions the setting free of phosphoric acid, we have the phenomena which occur pretty satisfactorily explained. That the formation of lactic acid occurs is indicated, he held, by the pathological lesions which occur in the disease.

He then reviewed briefly the more prominent lesions of yellow fever as found upon autopsy, consisting for the most part in rapid fatty degeneration of the liver, the coats of the stomach, extending well out along its vessels, sometimes resulting in hemorrhage, the kidneys, and brain, in all of which he traced the analogy to phosphoric acid poisoning. Poisoning by this agent, he added, causes the blood to become acid, just as it is found in yellow fever. The symptoms of the disease were then reviewed more fully, and the address closed with a short *résumé* of the treatment of the disease, including a number of experiments.

DR. WALTER P. GEIKE, of Ontario, Canada, then read a paper on

PNEUMONIA AS MET WITH IN VARIOUS PARTS OF THE DOMINION OF CANADA.

The first point he endeavored to establish was the frequence with which the disease occurred in various parts of the Dominion. In the furthest western portion, especially in the Westminster district, acute primary pneumonia is comparatively rare. It is much more frequently a secondary disease, complicating for the most part typhoid fever. Coming a little further eastward, it is said not to be common. Is this not, he inquired, because the settlers are as yet few in this region? In this part, too malaria, which is so important a factor in its influence upon all diseases, but especially this one, is not found. It occurs in the acute form in scattered settlements, assuming the more protracted form in the cities and in rapidly growing settlements. In the southern parts of Ontario, malaria is a frequent complication of the disease. The disease also tends to assume a low form. In Toronto, for instance, where malaria frequently complicates the disease, a low form is frequently encountered, which renders the prognosis much more grave. In many cases the disease seemed to be contagious, or perhaps more properly, the specific fever accompanying the disease appeared to be contagious. That the adynamic form of the disease should supersede in frequency the more acute form, is a striking fact. He admitted that in many cases the exhausted condition of the system from alcoholic or other excesses was responsible for this apparent inconsistency. But he thought bad drainage had more to do with the production of the disease than any other factor.

Coming to the province of Quebec, we learn that in Montreal pneumonia is frequent and is generally acute in form, unless when it affects enfeebled persons or those of intemperate habits. The very low form, thought by some to be contagious, is said to be very rare in Montreal, and its presence there as an epidemic is strongly questioned, as throughout the great Northwest malaria is not met with. There is little doubt that to the absence of malaria as well as to the similarity of climate is due the fact that pneumonia presents so many of the same features in these widely separated districts, in Quebec on the one hand, and in the Northwest on the other. The cases of pneumonia seen in New Brunswick, in Nova Scotia, in Newfoundland, and in Prince Edward's Land are the same. In conclusion, he said that it would be entirely too wide a field for the present occasion to introduce the question whether the disease is a local one or is the local expression of a specific infection.

Dr. Geike, in conclusion, stated that he did not consider pneumonia more frequent in malarial districts than elsewhere but when complicated by malaria the disease presents a much altered character and a higher mortality.

The Section then adjourned.

GENERAL SURGERY.

The Section met in the Congregational Church and was called to order at 3 P.M. by the President DR. W. T. BRIGGS, of Nashville, Tenn., who in a brief address of welcome opened the Section for work.

DR. CHARLES T. PARKES, of Chicago, presented a paper on

GUNSHOT WOUNDS OF THE ABDOMEN.

No subject has interested surgeons, he said, more than the treatment of penetrating wounds of the abdomen. In 1885 the whole number of recorded cases of operation for gunshot wounds of the intestine was but six. Since 1885, thirty-eight cases have been recorded with eleven recoveries, and surgical interference in appropriate cases is now the generally accepted view. The condition and appearances of the external wound give some indication as to presence or absence of penetration. A single wound of the abdomen affords a hope that the penetration has not taken place, but it is only a hope. Even the presence of a wound of entrance and exit does not positively indicate injury of the viscera. If there is a tract of tenderness continuous from the wound of entrance some distance, it is fair to infer that penetration does not exist. A large bullet-hole indicates penetration. When in doubt the wound of entrance should be enlarged. In this way the presence or absence of penetration can be determined, and with the usual precautions this does not increase the dangers.

In diagnosis much value cannot be attached to the subjective sensations. The unusually rapid appearance of tympanites in a region ordinarily dull, would indicate escape of gas into the abdominal cavity. Localized dulness in the region of the wound or in the dependent portion of the abdomen would indicate hemorrhage. The presence of blood in the urine indicates wound of the kidney, bladder, or ureter. Shock cannot be relied upon, but when present the probability of such injury is very great. The rare phenomenon of feces in the wound is a positive sign of perforation. The presence of persistent nausea and vomiting

also points to injury of the viscera. The absence of pulsation in one femoral vein indicates injury of the iliac vessel. Two cases were then reported.

In the treatment of gunshot injuries of the abdomen, incision in the median line is better in the majority of cases. There are exceptional cases in which enlargement of the original wound answers the purpose. The continuous suture answers every purpose, and as it can be inserted more rapidly than the Lembert, it is preferable. Silk is preferable to catgut in making the sutures. Where resection is required, two methods of procedure may be adopted. In cases where the mesenteric border cannot be saved, section should be made through the healthy bowel, and a triangular portion of the mesentery also removed. The two portions of the bowel are then brought together and secured with sutures, the first suture being introduced at the junction of the mesentery and intestine. In no case had he found it necessary to use more than one row of sutures. All raw surfaces should be covered with peritoneum. The second method is applicable in cases where the mesenteric border is not injured. In these cases the section does not involve the mesenteric border of the intestine. The injured portion is alone removed and the edges of the healthy bowel brought together with the continuous suture. Where the omentum is injured the hemorrhage is often severe, requiring the removal of a large portion of the structure. All slits and lacerations in the omentum should be closed by sutures. In perforation of the stomach there is no difficulty in closing the wound after it is found. Where there is no complication wounds of the stomach usually heal satisfactorily. In gunshot wounds of the liver the surfaces should be brought together by deep sutures. The same procedure may be employed in the case of the spleen, but where this organ is badly lacerated extirpation is indicated. Perforating wounds of the kidney call for extirpation. Perforation of the liver, spleen, or kidneys with a similar injury of the small intestine greatly increases the gravity of the case, and such cases will usually end fatally. Wounds of the bladder call for suture.

Special stress was laid on the necessity of seeking out all wounded bloodvessels, thus preventing the danger of primary or secondary hemorrhage. There should be a careful search made for all wounds of the intestine, the bowel being examined in a systematic manner. Tight sutures should be avoided, for these will lead to sloughing and extravasation. If the peritoneal surfaces are laid in contact and kept there for a few hours, adhesions will take place.

Dr. N. Senn, of Milwaukee, then read

AN EXPERIMENTAL CONTRIBUTION TO INTESTINAL SURGERY, WITH SPECIAL REFERENCE TO THE TREATMENT OF INTESTINAL OBSTRUCTION.

The indications in the treatment of intestinal obstruction are to remove or render harmless the cause of the obstruction, and the immediate restoration of the continuity of the intestinal canal. Where the cause cannot be removed, it is to be rendered harmless by forming an anastomosis between the portion of bowel below and that above. One hundred and fifty operations were performed on animals. The principal forms of intestinal obstruction were produced artificially, and the attempt was made to devise some new operation whereby the obstruction may be relieved when the removal of the cause is not possible. The length of time required in the performance of most of the present operations is their great contraindication. By simplifying the method of operation, the author had been able to lessen the time required. To prevent extravasation during the progress of the operation, the author had employed a narrow rubber band tied around the intestine with sufficient force to occlude it. He had never observed any injurious effects following the use of elastic compression.

The study was first directed to simple *stenosis*, which was produced by cutting out a semilunar portion of the bowel. (*a*) Traumatic stenosis from this cause becomes a source of danger from obstruction or perforation where the lumen of the bowel is reduced more than one-half. Where excision of the bowel is required for injury not more than one-half should be taken away. If more is required, circular excision should be resorted to. Longitudinal suturing of wounds on the mesenteric side of the intestine should never be practised, as such a procedure is invariably followed by gangrene and perforation, through interference with the blood supply of the portion of bowel corresponding to the mesenteric defect. (*b*) In circular constriction of the bowel, the immediate cause of gangrene of a loop of intestine is obstruction to the venous circulation, and takes place first at a point most remote from the cause of the obstruction.

Flexion (*a*) produced by partial enterectomy and transverse suturing of the wound. On the convex surface of the bowel, a defect an inch in width can be closed by transverse suturing without causing obstruction by flexion. In such cases the stenosis is subsequently corrected by a compensating bulging of the mesenteric side of the bowel. Closing a wound of such dimensions on the mesenteric side of the bowel by transverse suture, may give rise to intestinal obstruction by flexion, and to gangrene and perforation by seriously impairing the blood supply to and venous return from the portion of bowel corresponding with the mesenteric defect. (*b*) Flexion caused by inflammatory and other extrinsic causes, gives rise to intestinal obstruction only in case the functional capacity of the flexed portion of the bowel has been diminished or suspended by the causes which have produced the flexion, or by subsequent causes independently of the flexion.

Volvulus, as in flexion, gives rise to symptoms of obstruction when the causes which have given rise to a rotation upon its axis of a loop of bowel, have at the same time produced an impairment or suspension of peristalsis in the portion of bowel which constitutes the volvulus, or when a diminution or suspension of peristalsis follows in consequence of the rotation.

Invagination. Accumulation of intestinal contents above the seat of invagination, is one of the most important factors in preventing spontaneous disinvagination and in inducing gangrene of the intussuscipiens. Spontaneous reduction is not more frequent in ascending than in descending invagination. The immediate cause of gangrene is obstruction to the return of venous blood by constriction at the neck of the intussuscipiens. Ileo-cæcal invagination when recent can frequently be reduced by distentions of the colon and rectum with water, but this method of reduction must be practised with great care and gentleness, as over-distention of the colon and rectum is productive of multiple longi-

tudinal lacerations of the peritoneal coat, an accident which is followed by the gravest consequences. The competency of the ileo-cæcal valve can only be overcome by over-distention of the cæcum, and is effected by a mechanical separation of the margins of the valve, consequently, it is imprudent to attempt treatment of intestinal obstruction beyond the ileo-cæcal valve by injections per rectum.

In a study of the effects of *enterectomy*, it was found that in dogs, resection of more than six feet of the small intestine was uniformly fatal, the cause usually being the immediate effects of the trauma. Resection of more than our feet is incompatible with normal digestion, absorption, and nutrition, and often results in death from marasmus. In cases of extensive intestinal resection, the remaining portion of the intestinal tract undergoes compensatory hypertrophy.

It was also found that *physiological exclusion* of an extensive portion of the intestinal tract, does not impair digestion, absorption, and nutrition, as seriously as the removal of a similar portion by resection. Fecal accumulation does not take place in the excluded portion of the intestinal canal, which undergoes atrophy.

Objection was made to the various forms of suture used in *circular enterorrhaphy* for three reasons: first, the time required for their insertion; second, the danger of puncturing the bowel; and third, the interference with nutrition which they cause. The author recommends a modification of Jobert's invagination suture by lining the intussusceptum with a thin flexible rubber ring, and the substitution of catgut for silk sutures is preferable to Czerny-Lembert sutures.

The line of suturing, or neck of intussuscipiens should be covered by a flap, or graft of omentum in all cases of circular resection, as this procedure furnishes an additional protection against perforation. In circular enterorrhaphy continuity of the peritoneal surface should be secured where the mesentery is detached by uniting the peritoneum with a fine catgut suture before the bowel is united, as this modification of the ordinary method furnishes better security against perforation on the mesenteric side.

Intestinal anastomosis. The formation of a fistulous communication between the bowel above and below the seat of obstruction should take the place of resection and circular enterorrhaphy in all cases where it is impossible, or impracticable to remove the cause of obstruction, or where the pathological conditions which have given rise to the obstruction do not constitute an intrinsic source of danger. Gastro-enterostomy and jejuno-ileostomy should always be made by approximation with partially or completely decalcified perforated bone plates.

In making an intestinal anastomosis for obstructions in the cæcum, or colon, the communication above and below the seat of obstruction can be established by apposition with decalcified perforated bone plates, or by lateral implantation of the ileum into the colon or rectum. An ileo-colostomy, or ileo-rectostomy by approximation with decalcified perforated bone plates or lateral implantation, should be done in all cases of irreducible ileo-cæcal invaginations, where the local signs do not indicate the existence or occurrence of gangrene and perforation. In all cases of threatened gangrene and perforation, the invaginated portion should be excised, both ends of the bowel closed, and the continuity of the intestinal canal restored by making an ileo-colostomy by approximation with perforated decalcified bone plates, or by lateral implantation. The restoration of the continuity of the intestinal canal by perforated approximation plates or lateral implantation, should be resorted to in all cases where circular enterorrhaphy is impossible, on account of the difference in the size of the lumina of the two ends of the bowel.

In cases of multiple gunshot wounds of the intestines involving the lateral or convex side of the bowel, the formation of intestinal anastomosis by perforated decalcified bone plates should be preferred to suturing, as this procedure is equally, if not more safe, and requires less time.

Adhesion experiments. Definitive healing of an intestinal wound is only completed after the formation of a network of new vessels in the product of tissue proliferation from the approximated serous surfaces. Under favorable circumstances, quite firm adhesions are formed between the peritoneal surfaces within six to twelve hours, which effectually resist the pressure from within outward. Scarification of the peritoneum at the seat of approximation hastens the formation of adhesions and the definitive healing of intestinal wounds. Omental grafts, from one to two inches in width, and sufficiently long to encircle the bowel completely, retain their vitality, become firmly adherent in from twelve to eighteen hours, and are freely supplied with bloodvessels in from twenty-four to forty-eight hours. Omental transplantation, or omental grafting, should be done in every circular resection, or suturing of large intestinal wounds, as this procedure favors the healing of the visceral wound, and furnishes an additional protection against perforation.

Adjourned.

OBSTETRICS.

PROFESSOR DELASKIE MILLER, of Chicago, opened the Section meeting with an

INAUGURAL ADDRESS.

His chief duty, he said, was to extend a cordial greeting. More than sixty thousand physicians now in the practice of obstetrics in the United States, will accept the utterances of these meetings as the decision of the court of last appeal. Upon the subject of craniotomy, he remarked, "Under the new *régime* the interests of the living child will constitute a more important factor, and justly so, for in the ideal future the child shall be preserved by operations which shall not enhance the danger of the mother." With reference to the treatment of intrauterine pregnancy, he said: "The electric current may be directed through the ovum with the confident expectation of arresting its vitality without adding to the danger of the mother." On the puerperal state, he said: "Of first importance to insure success in obstetric practice is the adoption of a *régime* which shall render the puerperal woman aseptic. No argument is deemed necessary to establish this position."

The line of eminent men in our department of medicine is short when compared with that of the Orient, still in America we may present the names of obstetricians of past generations who would reflect credit on any age or part of the world. He then briefly referred to the labors of Bard, Dewees, Meigs, White, of Buffalo, Miller, of

Louisville, Wright, of Ohio, Hodge, James, Shippen, Francis, Channing, Gilman, and Elliott.

The following paper was forwarded by DR. J. BRAXTON HICKS, of London, and was read by proxy,

ON THE CONTRACTIONS OF THE UTERUS THROUGHOUT PREGNANCY, AND THEIR VALUE IN THE DIAGNOSIS OF PREGNANCY, BOTH NORMAL AND COMPLICATED.

Fifteen years ago he directed attention to the fact that during the whole of pregnancy the uterus contracts and relaxes, at intervals, usually varying from five to twenty minutes, and the object of this paper was to point out the practical application of the knowledge obtained by recognizing these intermittent contractions.

Up to the fourth month, it is better to employ external and internal palpation. Suppose that a single woman is brought to the physician, for amenorrhœa, of four or five months' duration, and as increased size is noticed by her friends, an easy opportunity is thus afforded to us to make a superficial examination: and thus, without implying any suspicion, we can ascertain whether there be any swelling in the uterine region, and if there be, whether it is permanently firm or of varying density. Should the latter be the case, then we have sufficient grounds to go further into the case, and proceed to internal examination.

There is a condition of the pregnant uterus, to which the author first called attention, wherein at about the fifth month, the uterus during the intervals is very flaccid, scarcely to be felt, except at one part, where a firm lump is to be felt, more like a tumor on one side; and this condition is very often associated with the death of the fœtus, which increases the deception, although it is true that in this condition of flaccidity the fœtus is more readily felt than when the uterus is firm. The diagnosis here is difficult, between simple pregnancy, pregnancy with tumor, and extrauterine fœtation until we feel the uterus contract, when the whole is resolved into a solid ball till relaxation again occurs. The more solid portion marks the position of the placenta.

In cases of pregnancy associated with fibroma, we are enabled, by watching these contractions of the uterus, to distinguish generally between the portion occupied by the pregnancy and that occupied by the tumor. But in cases in which the tumors are numerous and the pregnancy early, it is not so easy; sometimes it is impossible. The diagnosis between ovarian tumors alone, or in connection with pregnancy, is easy, being based upon the alteration in density of the tumor or tumors.

The diagnosis between extrauterine fœtation and normal pregnancy is more difficult, because our proof in the former case is of a negative character. If it be normal pregnancy suspected to be extrauterine, then the proof is more easy. Supposing we have a combination of the two, then a careful examination will, sooner or later, reveal which of the two is uterus.

In twin pregnancy, where sometimes one ovum is dead and small, or one complicated with hydramnios, we have difficulty in determining the nature of one, whether it be a separate tumor; but when we find, as the uterus contracts, the variable parts brought together into one spheroid, we may conclude that the whole is within the uterus; and palpation and the stethoscope will easily reveal the dual contents.

In case of overdistention of the uterus, as by hydramnios, we lose, to a large extent, these contractions, and there is, therefore, a difficulty in distinguishing between it and a large ovarian cyst, though, of course, we have other helps; and in cases of molar pregnancy of the solid kind, or where the ovum is dead and the uterus has become more resisting in consequence, we find often rigid contraction of its walls, lasting for days together.

Alteration of density, alleged in cases of soft fibromas of the uterus—never observed by the author—only interferes with the diagnosis between these cases and those of molar pregnancy and abortion, in which there is menorrhagia. The menorrhagia—continuous except in cases of extreme anæmia—and the rate of growth serve to differentiate soft uterine new formations from molar pregnancy and abortion.

Persistent contraction of the uterus is rare without some abnormal state of the ovum, by which it is sometimes caused; but it may be expected also to be detrimental to the vitality of the fœtus, interfering with its circulation.

Three cases were cited to illustrate the above propositions. In Case IV., of suspected extrauterine pregnancy, the author was asked to decide whether the fœtus in a woman, seven months advanced in pregnancy, was placed within or without the uterus. The size of the abdomen was in correspondence with that of normal pregnancy, and the existence of a fœtus was also without doubt. The abdomen was examined only externally at first, and was soft, with only the fœtus to be felt; but in a few minutes the fœtus was less and less felt, till the abdomen was occupied by a firm pyriform mass which could easily be decided to be the uterus in contraction. This was quite evident when the contraction passed off, leaving the abdomen as soft as before, and the fœtus easily made out, as at first.

Dr. Hicks concluded with the following *résumé*:

I. During the whole of pregnancy, the uterus contracts at intervals, varying much, but commonly from five to twenty minutes, remaining contracted for a variable time—from three to five minutes.

II. If we place our examining hand on the uterus at the time of contraction, the uterus will be firm, pyriform, and the fœtal parts not easily detected, in general. If we place our hand in a state of repose, or allow it to remain on till the firm condition has passed away, then the outline of the uterus is found indistinct, sometimes not to be felt at all; while the fœtal parts are more or less easily detected, and can often be pressed by the fingers into various positions.

III. By noticing these facts we are enabled with ease, in general, to decide as to the existence of normal pregnancy: to diagnosticate between this and various tumors, both uterine and abnormal pregnancies; between pregnancy and distention of the bladder, and other conditions easily recognized by the practitioner.

IV. These intermittent contractions have the physiological use of emptying the uterine veins and thus changing the highly carbonized blood for that more aërated.

V. From some observations he is inclined to think that there is some closely constant relationship between this highly carbonized blood-accumulation and the fœtal movements, and between the fœtal movements and uterine contraction.

VI. He can confidently commend to the profession this additional help in the diagnosis of pregnancy, one easily recognized and easily learned. In his own practice it has proved to be of the greatest service for many years.

PROFESSOR A. R. SIMPSON, of Edinburgh, expressed the indebtedness of obstetricians to the rhythmic contractions of the pregnant uterus and their value in the diagnosis of pregnancy. He always insisted on the importance of attending to the alternate hardening and softening of the uterus, especially during the early months when, as yet, the fœtus had not become so developed as to be recognizable to touch or auscultation, and in cases in which the ovum had become addled, or was undergoing degeneration. As regards the physiological effects of these contractions, he thought it important to note the results of them at the close of pregnancy and the commencement of labor. There had been discussion between Küneke and others as to whether the uterine sinuses remained distended with blood or not. The probability was, as indicated by Dr. Braxton Hicks, that during contraction the uterus became anæmic. In Braun's frozen sections one could see that the walls of a uterus caught in diastole had had its vessels filled, whilst in the uterus caught in systole, when the walls were contracted and thickened, the vessels were empty. During each contraction the blood expelled from the uterus would first distend the blood-vessels in the cervix uteri and the vaginal walls. As a consequence of the engorgement of the capillaries of these structures, there took place exudation, increased mucous secretion and the softening of the tissues generally which was sometimes called vital dilatation, and the full development of which was so important for enabling the practitioner to form a favorable prognosis in ordinary labor. The sign was of especial diagnostic value at the third month—after Hegar's sign has been elicited—on bimanual palpation.

DR. CHARPENTIER, of Paris, narrated the history of a case of pregnancy complicated by hydramnios, in which Braxton Hicks's sign had been of very great aid.

DR. A. F. A. KING, of Washington, said the only detracting circumstance applying to the method of diagnosis under consideration, is the impossibility of differentiating the intermittent contractions of pregnancy from those produced under manipulation, in case of foreign bodies, such as polypi, retained menses in the caverna uteri, the positive diagnosis of pregnancy during the first three months, being practically impossible.

DR. DUNCAN C. MACCALLUM, of Montreal, then read a paper on

VICARIOUS MENSTRUATION.

He stated that the possibility of hemorrhage taking place from some other part of the body than the uterus as the immediate result of the suppression of the menstrual function, had been admitted from an early period by medical authorities, and accepted as an established fact by the profession generally.

As there appears to exist a discrepancy of opinion regarding what really constitutes vicarious menstruation, he said it was of great importance for the proper understanding of the subject, that agreement should be arrived at on this point. If the term be held to include all cases of hemorrhage occurring at the menstrual epoch, the menses being absent, and no other possible cause for the hemorrhage being present, whether the phenomenon be repeated or not at one or more succeeding menstrual periods, the cases would be very numerous, and there are probably many physicians in active practice who have met with one or more examples.

Suppression of the menses is a condition which frequently engages the attention, and comes under the care of the practical physician, but it is seldom attended by hemorrhage. It would appear, therefore, that something must be superadded to the amenorrhœa—some condition of the vasomotor nerves, or of the vessels of the part from which the blood escapes.

He then gave the details of the four cases of vicarious hemorrhage which had come under his observation—two of hæmatemesis, one of hæmoptysis, and one of epistaxis, and concluded by saying: Each of these cases fulfils the three main conditions demanded to constitute what he conceived to be a case of vicarious menstruation, namely—(a) Absence of a flow of blood from the uterus at the menstrual epoch. (b) An eruption of blood from some other organ. (c) Absence of any cause for the ectopic hemorrhage, other than arrested menstruation. It fulfils in the relief of vascular tension one of the principal objects of the menstrual discharge. It is clearly a vicarious hemorrhage.

DRS. BARTLETT and NELSON narrated histories of cases of alleged vicarious hemorrhage.

PROFESSOR T. LAZAREWITCH, of St. Petersburg, then presented, through the Secretary, a

DESCRIPTION OF A NEW NORMAL FORCEPS.

Inspecting the child's head after each forceps operation, and sketching the impression, he found that when the impressions were made on the cheek bones they were at a distance from the protuberance of the temporal bones, equal to half of the arc of the blade.

The greater the surface on which the blades act, or, the more curved inward the blades are, the greater will be the expelling power. Dr. Lazarewitch's parallel forceps, whatever the size of the head, preserve the same grasping power which in other forceps diminishes in proportion to the size of the head. He has constructed a lock that prevents slipping, by preserving the same inclination of the blades, whatever the size of the head.

The lock is constructed with a tenon entering freely into the large mortise, made in each branch of the forceps, the tenon being fixed by a screw in one branch, which is retained at the desired distance from the other by a projection constructed on each side of the tenon. This lock permits mobility by turning each half of the forceps on the longitudinal and transverse axes.

The conoid form of his *normal* straight forceps enables the operator to extract the head without drawing out the blades, and to place the blades in any one of the diameters, transverse, oblique, or conjugate.

His description of the forceps is as follows:

Made of steel, nickel plated; 13½ inches long; the blades have some elasticity, their surfaces smooth and polished. At a distance of ¾ of an inch from the tips, the blade is 1⅔ inches wide, and from the point grows narrower, until it is about ½ of an inch at the neck. The fenestra—elongated oval—⅞ of an inch wide, and 3¾ inches long. The cephalic curve has a radius of

7¾ inches. The inner surface of the handle is 1 inch in width, and 3¾ inches in length. The tenon of the lock is ¾ of an inch wide, 2¾ inches long, and ½ of an inch thick. The mortise is $\frac{9}{16}$ of an inch long and is about ½ of an inch wide.

He has employed his straight forceps, with the parallel handles, several times in the low operation, nine times in the high operation, with perfect success; with the latest improvement, in two cases.

He has successfully applied his forceps in one case of breech presentation, without any injurious compression. In such cases the blades must be applied as far as possible upon the bistrochanteric and transverse diameters.

GYNECOLOGY.

The Section met in Masonic Temple at 3 P. M., the PRESIDENT, DR. H. O. MARCY, of Boston, in the Chair.

The proceedings were opened by a few fitting words of welcome on the part of the President, especial allusion being made to the part which Americans, and especially Marion Sims, had played in the development of this branch of medicine.

DR. NATHAN BOZEMAN, of New York, then read a paper upon

THE GRADUAL PREPARATORY TREATMENT OF THE COMPLICATIONS OF URINARY AND FECAL FISTULAS IN WOMEN,

including a special consideration of the treatment of pyelitis by a new method, and the prevention of the evils of incontinence of urine by a new system of drainage. He referred at length to his well-known method of preparatory treatment for operation upon fistulas of various kinds and various degrees of severity, exhibiting and explaining the appliances which he is in the habit of using for producing dilatation and removing adhesive bands. The great difficulty has been hitherto so to control the escape of urine that its annoying and injurious effects could be obviated. He believed that that question was now solved by the use of a combined dilator and urinal, consisting in a hollow metallic receptacle, perforated with a few holes upon its upper surface, and provided with a long rubber tube which projects from the vagina. This instrument may be considered as supplemental to or developed from the hard-rubber vaginal dilators and the soft-sponge bag dilators which he has been using for many years. This method of treatment has been recently extended by him to certain cases in which, in addition to an urethro-vaginal fistula, pyelitis had also developed. Several ingeniously constructed probes and catheters were shown, by means of which he had been able to explore the ureter even to the pelvis of the kidney, to complete a diagnosis of pyelitis, and, by irrigation of the diseased organ, to bring about great improvement in the patient's condition. The operative procedure for accomplishing this end he has termed kolpo-uretero-cystotomy. He summarized his views as follows:

1. That the importance of the complications of fistula in the female has not been sufficiently appreciated.

2. Kolpo-kleisis is an unjustifiable operation, and leads to cystitis, pyelitis, etc.

3. The combination of drainage with dilatation as here expounded is believed to be productive of most useful results.

4. Some form of drainage is suitable for every case in which a vesico-vaginal fistula exists.

5. For such cases drainage will prove a means of great relief.

6. It is believed that this method of operation will prove of great service in the treatment of pyelitis and some other renal diseases.

DR. GRAILY HEWITT, of London, in opening the discussion, made a graceful allusion to the pleasure he had experienced in being in America at this time, and generously gave full credit to American gynecologists for the work which they had done. He considered that Dr. Bozeman's paper marked a distinct advance in the treatment of urinary fistulas; and the suggested operation for pyelitis was directly in the line of conservative surgery, and an improvement upon nephrotomy or nephrectomy.

DR. ADDINELL HEWSON, of Philadelphia, referred to his satisfactory experience in the use of the author's method of dilatation in the preparatory treatment of fistulas. He had also derived great advantage from the injection of a current of carbonic acid gas highly charged with sulphuretted hydrogen (exactly the same treatment that is followed in Bergeon's method of treating pulmonary phthisis *per rectum*) into the vagina and bladder. The treatment was usually continued for twenty minutes at a time, and satisfactory dilatation resulted.

DR. WATHEN, of Louisville, read a paper upon

RAPID DILATATION OF THE CERVIX,

stating at the outset his predilection in favor of this operation by means of steel dilators, especially in the treatment of dysmenorrhœa and sterility. Tents of all kinds were believed to be more or less unsafe, and a two-bladed instrument was preferred to bougies or any other form of instrument for this purpose. The operation should always be done with the greatest regard to antisepsis, and in case he dilatation is to exceed three-quarters of an inch, general anæsthesia to a moderate degree should be first produced. The form of dilator which he used had parallel blades which were thickened at the tips, and enabled one to dilate as thoroughly at the os internum as at the os externum, the blades not giving or springing, and thus producing unequal dilatation, as is too apt to be the case with such instruments as Goodell's for example. He considered that this method of operation could be substituted for other means in almost every case in which dilatation is indicated.

DR. A. MARTIN, of Berlin, in opening the discussion, sketched the development of the idea of dilatation since it was first propounded by Simpson, forty years ago, and alluded to the great changes which had occurred to the operation during that period. He quite approved of the author's idea of making the dilatation ample at the os internum, if it were done at all. For himself, however, he did not see the necessity for doing the operation frequently. The womb could be explored after slight dilatation, perhaps with the finger, and the curette could then be used if the question were one of diagnosis as to the character of the endometrium. He sometimes had occasion to divide the cervix with a knife, after which the interior of the organ could be ex-

plored, and the wound then closed as in the ordinary Emmet operation.

DR. WEEKS, of Portland, Me., thought the operation contraindicated in cases in which there was faulty condition of the ovaries and tubes. It was not an operation which was devoid of danger. He had lost a patient who was seized with acute peritonitis on the fourth day after a second operation for dysmenorrhœa.

DR. REED, of Ohio, deprecated the general advocacy of this method of treatment.

DR. GOELET, of New York, thought the great end to be attained was to produce dilatation to a certain degree, and then retain it by the use of a stem pessary for a sufficient length of time.

DR. TRENHOLME, of Montreal, laid stress upon the statement that those cases were not suitable for operation in which there was either uterine congestion or any disease of the tubes or ovaries. The patient should be examined just after menstruation is ended, and if any of these conditions are found no operation should be done. After the operation he approved of the use of a curved stem.

DR. GLISAN, of Portland, Oregon, had always obtained satisfactory results from the operation, and without especial attention to antisepsis.

DR. REEVES JACKSON, of Chicago, deplored the frequency with which the operation is done. He thought it useless except for purposes of exploration.

DR. NOTT, of Texas, believed that the field for the proper performance of the operation was a limited one.

DR. BURNS, of Allegheny, Pa., preferred to dilate the uterus, in proper cases, with hard rubber stems, leaving them in for several days and securing proper drainage.

DR. BALLS-HEADLEY, of Melbourne, Australia, still found Sims's operation of posterior section satisfactory in cases of stenosis attended with dyspnœa. He could not understand the great enthusiasm in America upon the subject of rapid dilatation.

DR. HOFF, of Ohio, obtained satisfactory dilatation with tents made of the pith of the cornstalk and wrapped with absorbent cotton.

DR. MCBURNEY, of Detroit, found as the result of a great many measurements upon the cadaver, that dilatation was anatomically unnecessary in most cases, and believed that he accomplished the same result, namely, the relief of congestion, by the use of suitable vaginal applications.

DR. DORRANCE, of England, still followed Sims's plan of cutting the cervix from the os internum to the os externum, keeping the wound open by means of a piece of lint laid within it, in those cases which are ordinarily treated by dilatation. During gestation, if it be desired to dilate the cervix, he uses an aseptic sponge tent.

DR. ANDALE, of Pittsburg, had never seen any bad results from the operation. He preferred steel dilators to tents. He had often seen sterility relieved by the operation.

DR. SATTERLEE, of Kentucky, had never had occasion to perform the operation, believing that the same results could be obtained by vaginal applications of hot water.

DR. WATHEN, in concluding, stated that he did not hesitate to perform the operation in his office, in suitable cases. He did not accept Emmet's dictum, that there was no such thing as congestive dysmenorrhœa. If Emmet did not believe in the conditions for which the operation was required, he could not consistently do it, hence his opposition to it. He would do the operation only in cases in which equally good results could not be obtained by milder means.

DR. T. MORE-MADDEN, of Dublin, forwarded a paper entitled

ON THE CAUSES AND TREATMENT OF BARRENNESS,

which was read by the Secretary.

It presented, in tabular form, a statement of the causes of sterility in five hundred and twenty-eight of the cases of infecundity occurring in married women, within the childbearing period of life, that had come under his observation. The cases may be roughly divided into four classes, viz.: 1st. Those in which barrenness was occasioned by sexual impotency or some physical impediment in the passages from the vulvar orifice to the ovaria. 2d. Cases of true sterility, or conceptive incapacity from deficiency congenital or acquired, structural disease, arrested developments, supra-involution, etc., of the uterus or from analogous morbid conditions of its appendages. 3d. Cases of barrenness from constitutional causes. 4th. Cases in which the causes of infecundity were apparently moral rather than physical, such as sexual incongruity, etc.

The most frequent of these causes of sterility is stenosis of the cervical canal. And, as he believes that the operative treatment of such cases, simple as it is deemed by some, requires more consideration than it generally receives, and frequently proves worse than useless from the disregard of certain details and precautions which he considers essential, he ventured to recommend the adoption of a method of procedure and the use of instruments which he had found advantageous in the curative treatment of stenosis in three hundred and eighty cases of obstructive dysmenorrhœa and sterility traceable to this cause.

The essential features of the method of treatment now referred to are the separation by cutting and simultaneous forcible expansion of the affected parts, followed by dilatation during the period of cicatrization, so as to prevent their subsequent contraction, and thus to secure the permanent patency of the previously occluded passage. To obtain this result he employs three instruments, namely: a special form of uterine director, which can, generally speaking, be introduced into any cervical canal, however narrow, and along which a serrated, triangular-guarded knife is made to travel up through the os internum; and, thirdly, a uterine dilator of great power, by which any required degree of cervical expansion may be effectually secured and accurately gauged.

The influence of uterine flexions in the prevention of pregnancy and the treatment he adopts in cases of sterility dependent thereon were described. He then dwelt on the subject of conceptive incapacity from morbid conditions of the Fallopian tubes, as he regards stenosis, as well as occlusion of these ducts by vaginitis and its results, such as hydro- and pyosalpinx, as far more common causes of sterility than is generally recognized. Moreover, he also holds that such tubal diseases may, in many instances, be efficiently dwelt with without resort to the serious operative procedures—*i. e.*, the removal of the uterine appendages, which, by some

surgeons, are considered invariably necessary, and are by them so freely employed in such cases. Therefore, he referred at some length to those less heroic alternative measures, such as aspiration and catheterization of the Fallopian tubes, the feasibility and the successful results of which, in appropriate cases of this kind, he has demonstrated clinically.

Dr. Gordon, of Portland, Me., believed that sterility was not often due to stenosis of the canal. Other important causes were vaginismus, a diseased uterine mucous membrane, which was usually due primarily to a displacement of the uterus, and disease of the tubes and ovaries.

Dr. Reed, of Ohio, thought that Hodge as well as Graily Hewitt, deserved great credit for suggesting the treatment of these disorders by mechanical supports.

Dr. Graily Hewitt modestly admitted that he but took up Hodge's suggestion and applied it to anterior displacements, as Hodge had to posterior ones. Besides dilatation as a means for relieving sterility and dysmenorrhœa, the uterine canal should also be straightened, and both ends were often accomplished by the same means.

Dr. Smith, of Montreal, suggested that disease of the testicles must not be overlooked in the treatment of sterility.

Dr. Nelson, of Chicago, observed that the uterus must not only have no gross lesions, but its mucous membrane must also be susceptible of normal congestion in order to conception. Abuse of coitus was also believed to be a potent cause of sterility.

Therapeutics and Materia Medica.

The President, Dr. Traill Green, of Easton, opened the proceedings of the Section with a short address, dealing largely with the history of the study of this branch of medicine in the United States, and referring in laudation to Morgan and Kuhn, the first teachers of materia medica in America. He also spoke in complimentary terms of the recent works on therapeutics by American authors, more particularly those of Drs. George B. Wood, Stillé, Robley Dunglison, and H. C. Wood, and referred to the two dispensatories, printed in this country, as triumphs of medical authorship. He impressed upon his hearers the fact that the rational use of drugs rests upon a knowledge of their physiological action, and that for this reason experiments on the lower animals are necessary and of great value.

Dr. C. D. F. Phillips, of London, in reply, thanked Dr. Green for his kindness to all the members of the Section, and stated that Englishmen all owed much to the works of Stillé and the elder and younger Wood, each new edition of whose books was always welcomed in England.

The Section, after transaction of other business, adjourned to meet on Tuesday afternoon at 3 o'clock.

Diseases of Children.

The Section was called to order by The President, Dr. J. Lewis Smith.

Dr. Saint Germain, of Paris, forwarded a paper on

PREPUTIAL DILATATION AND IGNIPUNCTURE IN PLACE OF CIRCUMCISION AND TONSILLOTOMY,

which was read by the Secretary, and presented the following conclusions:

In view of the frequency of these two classes of cases, and of the satisfactory results obtained without risk to the patients, ought we not to consider the substitution of preputial dilatation and ignipuncture of the tonsils in the place of circumcision and tonsillotomy an appreciable surgical advance?

Dr. A. March, of Illinois, thought simple incision the more satisfactory and radical measure, and that there is but little danger from incision. We have trouble only about once in three hundred times.

Dr. Lewis A. Sayre, of New York, read a paper on the

DELETERIOUS RESULTS IN CHILDREN OF A NARROW PREPUCE AND PREPUTIAL ADHESIONS.

He partially reviewed the literature of the subject to establish his claim to having been the first to call attention to the significance of these cases. He recommended as little cutting as possible, just enough to permit of preputial retraction. He inserts a grooved director under the prepuce, and then cuts all contracted tissues, and no more, with a curved bistoury. If necessary, a slight cut may be made with scissors. He strongly objects to the general and unjustifiable mutilation of the prepuce. Enough should always be left to form an adequate covering for the glans. It is very common to mutilate the prepuce of small children for symptoms that do not justify operative interference. He reported a number of cases of reflex disturbance from constriction or adhesion of the prepuce, or the collection of smegma, showing the prompt relief afforded by circumcision and the removal of smegma.

Dr. De Forrest Willard, of Philadelphia, was glad Dr. Sayre had modified his former radical ideas as to the value of circumcision. He did not doubt that reflex symptoms result from preputial contraction, and he had seen many such cases. It is often that children have a slight agglutination of the prepuce and glans, and they require nothing but a stripping back of the prepuce and cleansing of the glans, which will, in many cases, take the place of all operative interference. Long prepuces are often mistaken for contracted ones, and a little care in stripping back will fully expose the glans. Care must be taken to avoid paraphimosis. In case of swollen glans it is well to make suitable intrapreputial injections for several days. In older children and adults there is less to be hoped for from dilatation, and circumcision is more often called for. He thinks the prepuce is only intended to cover and protect the glans during infancy and childhood.

Dr. Sayre thought the daily stretching and stripping back of the prepuce cruel and inhuman. Slight nicking is a simpler and better plan.

Dr. Lewis H. Sayre preferred always to operate in all cases having symptoms pointing to organic disease of the cord, thereby giving otherwise hopeless cases the benefit of every doubt. He cited the almost complete cure in this way of a case circumcised by him after having been diagnosticated by the leading neurologists of the country as a case of pseudo-hypertrophic paralysis.

Dr. Booker, of Baltimore, objected to Dr. Willard's "stripping plan," on the ground that it would lead to masturbation.

Dr. Willard thought masturbation would not be

induced if the prepuce is not tight, as one that slides back freely and easily causes no erethism.

DR. I. N. LOVE, of St. Louis, suggested that the majority of cases of preputial irritation called for the carrying out of the Mosaic law.

DR. GORDON, of Portland, Me., also favored the rabbinical procedure, so as to insure the daily stripping and washing, as mothers are not to be depended on to do this.

DR. P. R. FURBECK, of Gloversville, N. Y., related cases showing prompt and permanent relief from one complete dilatation. He did not favor repeated dilatation.

DR. J. LEWIS SMITH called attention to the causative relation between preputial and urethral stenosis, and collections of smegma, to inguinal hernia in children. Cases of hernia in children have been relieved by circumcision. The hernia is caused in these cases by straining efforts at micturition.

OPHTHALMOLOGY.

MONDAY, SEPTEMBER 5TH.

THE PRESIDENT, DR. J. J. CHISOLM, of Baltimore, in the chair.

DR. A. MOOREN, of Düsseldorf, Germany, read a paper on

EYE TROUBLES IN THEIR RELATION TO OCCIPITAL DISEASE.

He began by recalling to the minds of his hearers that the physiology of to-day places the centre of vision in the cortex of the occipital lobe, and that this localization was first pointed out by Huguenin, who by a section showed a defect in the cortex of these lobes in a case of optic atrophy with amaurosis of the left eye, existing from earliest childhood. He further referred to the experiments of Munck on this same subject as classical, and stated that this observer's conclusions were far-reaching and exact. Willhand formulates the results of his investigations thus, that the color centre is placed on the most exterior part of the occipital lobes, that beneath it we have the centre for acuteness of vision—the centre for the sense of space.

In the third layer there exists, next to Gratiot's visual radiations, the light centre—that is to say, the centre for the visual field. Destruction of the last layer, of course, destroys the functions of the other two, but it is equally evident that destruction of the others does not destroy the centre for the visual field. After describing the conditions of the optic nerve, as seen during the presence of lesions in these regions, he went on to state that though there are "neuropathic individuals who pretend to see from time to time under the symptoms of a scotoma scintillans by serious attacks of hemicrania, the objects half cut," that he had failed in every instance to discover "objectively in such patients any anomaly of this sort." Seguin and Cuschmann place the centre of optic perception in the cortex cuneatus and the first occipital convolution.

DR. CHISOLM, of Baltimore, exhibited a patient suffering from a tumor of the occipital lobes, which had entirely eroded the skull, so that the brain could be felt through the scalp. This growth was first noticed two years prior to the present date, about which time hearing was dulled in the left ear, while the sight of the right eye became impaired. At this time, however, he could still read clearly with the left eye. Five months since both of the nerves showed incipient atrophy, but nevertheless vision was good in the left eye. In the last two or three months both eyes have failed.

DR. LEARTUS CONNOR, of Detroit, then read a paper

ON THE USE OF HOT WATER IN THE TREATMENT OF EYE DISEASES.

He recommended the use of water as hot as could be borne, and stated that the temperature of hot water applications to the eye should never be less than 105° F. or more than 140° F. Temperature below 105° F. was absolutely injurious. The advantages of this treatment consisted in its cheapness, safety, and the fact that it can always be obtained. He believes that poultices should never be used to the eye for many reasons, and that the hot compress is not so good as the plain hot water application. He recommends also the immersion of the eye in hot water by the inversion of a small tumbler which will fit in such a manner as to prevent leakage over the face.

In the discussion, DR. THOMPSON, of Indianapolis, deprecated Dr. Connor's rejection of the "time-honored poultice," and praised very highly the use of slippery elm, sassafras, and chamomile poultices in many instances of inflammation. He also asserted that, in his experience, every case did not do so well with hot water as might be hoped from Dr. Connor's paper, and that in these instances cold water was of service. He thought the matter depended largely on idiosyncrasy.

The Section then adjourned.

TUESDAY SEPTEMBER 6TH.

GENERAL SESSION.

The second General Session of the Congress was called to order by THE PRESIDENT, DR. N. S. DAVIS, promptly at 10 o'clock.

DR. AUSTIN FLINT, of New York, delivered an address on

FEVER, ITS CAUSES, MECHANISM, AND RATIONAL TREATMENT.

(See p. 287.)

The address was listened to with general and unabated attention. At its close the President announced that it had been decided to postpone the address of Professor Semmola until Wednesday morning, in order to shorten the morning sessions and to avoid interfering with the work of the Sections, which were announced to convene at 11 A. M.

SECTIONS.

MEDICINE.

Owing to a scarcity of papers, the Section held no morning session, but assembled promptly at 3 P. M.

DR. JOSEPH KAPOSI, of Buda-Pesth, Hungary, read a paper on

THE PREVENTIVE POWER OF VACCINATION.

Is it true, he asked, that a less number of vaccinated individuals get smallpox than of unvaccinated? This is

difficult to answer, for to do so it would be necessary to separate the vaccinated from the unvaccinated in smallpox epidemics; and this is not possible. It is claimed, on the one hand, that the vaccinators cannot establish the truth of their claimed immunity. The anti-vaccinationists must rely upon small numbers of cases; and, for the most part, their observations have been among badly vaccinated individuals. This is, of course, no direct answer to the question. It is asserted that the unvaccinated suffer in larger numbers from smallpox than the vaccinated; but this is answered by the anti-vaccinationists by the statement that if this is the case, t is so because the unvaccinated are found among the poor, who are more exposed to all diseases, and who are more likely to succumb to diseases than the higher classes who are less exposed.

Further, it has been established that some diseases can be communicated by vaccination. The anti-vaccinationists therefore say that we conclude that vaccination is not only a useless procedure, but that it is positively dangerous. Such was the statement of the arguments against vaccination.

In the first place, are unvaccinated persons more subject to disease than are the vaccinated? If so, is this fact due to their lack of vaccination? This question could be readily answered if we knew the lethality of all diseases among the vaccinated and the unvaccinated, and if we could compare these statistics with the mortality of smallpox patients. Conclusions would, in other words, be possible, if we know in the case of each patient whether he had previously been vaccinated or not.

He had introduced this method of investigation into each of the nineteen hospitals of his district, and had met with considerable success, during the nine months in which it has been in operation, owing to the efficient coöperation of the gentlemen in charge of these institutions. The reports showed that of about 20,000 patients admitted in that time to these hospitals, 16,135 were vaccinated. Of these there died, from every cause, 1306. There were 2437 unvaccinated patients, of whom 321 died; showing, in the first instance, a mortality of about 8 per cent., in the latter 13 per cent. The mortality from all diseases is thus greater among unvaccinated than among vaccinated. But how is it in smallpox? The statistics of these hospitals showed that amongst the vaccinated patients the mortality of smallpox was 6.66 per cent.; while in the unvaccinated it was 49.68 per cent., or nearly half. It would not now be correct to assume that the relation of immunity conveyed was, therefore, so great as 800 per cent. Two factors must be considered as producing this result; in the first place, the vaccination; and, in the second, the difference of constitution on the part of the individual. As nearly as could be determined, difference of constitution was responsible for 50 or 60 per cent. of this difference, the rest being fairly attributable to the lack of vaccination. It is safe, therefore, to say that the unvaccinated are exposed to about five and a half times greater danger of death from smallpox than are the vaccinated.

The same series of observations show that among 19,738 non-smallpox patients, 2437 had previously been vaccinated, or 12.7 per cent. There were in that period in the hospitals 1113 cases of smallpox. Of these 1113 cases, in order to make the ratio the same as among non-smallpox cases, there should be 141 unvaccinated; but instead of this number, there were 465, or nearly 45 per cent.

Statisticians, in observing the mortality of vaccinated and unvaccinated cases, have confined their observations almost entirely to smallpox patients; but of what value is it simply to say that so many were vaccinated, while a certain other number were not vaccinated? In Buda-Pesth, a city of 20,000 inhabitants, the coroners have been required to report to the essayist whether or not each of the cases coming under their observation had or had not been vaccinated.

The results were even more striking than in the previous observations. The same proportions are found to exist in all periods of life.

In regard to the dangers of vaccination it is impossible to give a perfectly satisfactory answer, owing to the impossibility of determining in most cases whether or not diseases coming on after vaccination are in any way related to the vaccination. Reports were made to the essayist from the same sources in regard to the frequency of syphilis in vaccinated subjects; and, on the other hand, of the proportion of vaccinated and unvaccinated among syphilitics; and, in like manner, of tuberculosis and cutaneous diseases. Only in the instances of cutaneous diseases and syphilis were the statistics sufficiently complete to admit of deductions. The danger of inoculation of these diseases was 13 per cent. If this be correct, he concluded that, as the danger of smallpox was lessened several hundred per cent. by vaccination, whereas this operation exposes to a danger of but 13 per cent., the immunity which it conveys is at the worst cheaply purchased.

DR. C. A. LEALE, of New York, stated that he could verify most of the statements made. His opportunities for investigation in this field had been extremely large, and all the testimony went to prove the protective power of vaccination. That diseases could be communicated by vaccination, there could be no doubt, but the frequency of such inoculation is very small. During more than a year not one case of smallpox has occurred in New York, a fact due, he thought, to the systematic methods of vaccination in practice there.

DR. W. M. WITMARSH, of England, proposed a number of questions eliciting the facts that both bovine and humanized virus are used in Hungary; that but one child, so far as he was aware, had died directly as a result of vaccination, although it is difficult to state the relation of many other cases to the operation.

DR. LYNCH, of Baltimore, thought that no one could examine the statistics without arriving at the conclusion that vaccination does protect from smallpox, if, indeed, it did not also convey some degree of immunity from other diseases. He referred to the prevalence of smallpox in Washington in 1863, when the disease was confined, as is shown by accurate statistics, almost exclusively to the unvaccinated.

DR. KAPOSI stated that he had papers to prove that the late Dr. Keller, of Vienna, whose work had proved probably the most formidable weapon of the anti-vaccinationists, had deliberately distorted facts in order to favor that sect, and asked that a committee be appointed to examine these papers and report at a subsequent session.

DR. W. M. WHITMARSH, of England, read a paper entitled

VACCINATION AND PASTEUR'S TREATMENT.

The treatise consisted of two distinct parts, the former considering vaccination as a preventive of smallpox, the latter the treatment of rabies by Pasteur.

The essayist did not feel justified in affirming that vaccination does bestow an immunity from smallpox, although he would admit that while pock-marked faces were common in London forty years ago, they are infrequent at the present time. Many other diseases have become relatively as much reduced in their frequency as has smallpox, without however, the aid of any such process as vaccination, as is the case with typhus fever, and the plague. This should make us cautious in our conclusions. He closed this part of his address with the petition that all who heard him would use calf and not humanized lymph, as there could be no doubt that the danger from the conveyance of disease by it is much less.

Pasteur's treatment he reviewed at considerable length. He called attention to the apparent errors in the processes, as well as in the selection of cases, and the conclusions arrived at by Pasteur in regard to the curative value of his treatment. That rabies is due to the microbe to which it is assigned by Pasteur is by no means established. The same microbe has been found in the saliva of healthy individuals, and it has been shown by one investigator that a fatal disease can be produced in rabbits by the inoculation of this parasite after the manner of Pasteur. Further, control experiments have not been undertaken by Pasteur. In this connection the essayist proposed the adoption of the test to which vaccination was put in England forty years ago, namely that criminals should be given the choice of meeting their lawful punishment or of undergoing the inoculation according to the method of Pasteur, then, after three months to have a small wound made in their integument and into it place a small amount of virus from a rabid dog. Investigations of this character would soon demonstrate whether or not the inoculations convey an immunity. Cases are unquestionable in which the animal which has bitten the individual afterward resorting to the Pasteur treatment has not been rabid, as supposed. The essayist narrated at some length several such cases which were well authenticated.

He had been strongly impressed by the fact that dogs are permitted to make their abode in the laboratory of Pasteur and eat as freely as they desire of the rabbits, even of the rabid (?) medulla used in the inoculations, and yet he was assured by an assistant that their doing so was entirely devoid of danger.

Finally, he asserted, it has been established beyond doubt that in several cases death has followed the inoculations of Pasteur in which the symptoms displayed not the features of hydrophobia, but of a disease indentical in character with that witnessed in the rabbits which are made to succumb to the inoculations. It is not improbable, therefore, that as a result of these inoculations there has been produced a disease which from analogy should be called Pasteurophobia, in its results far from dangerous. He asked that before risking human beings to the dangers of these inoculations, further demonstrations of their safety and value should be awaited. Bad as it is to be bitten by a mad dog, it is far worse to have injected into one's abdomen ten times as much mad rabbit when, in all probability, the patient has not been bitten by a rabid dog.

DR. C. A. LEALE, of New York, thought that in most of the cases supposed to have been bitten by rabid dogs the animal was not in reality mad, and that the successful results of Pasteur's treatment were largely due to this. The effect of such alarms upon the nervous systems of the delicate can be readily imagined. In conclusion he hoped that in the light of our present knowledge the profession will not resort to Pasteur's method.

DR. WELCH, of Philadelphia, expressed his belief in the preventive power of vaccination and his preference for humanized virus. The danger of inoculation of other diseases with the vaccine virus he did not consider a sufficient argument against vaccination.

Adjourned.

GENERAL SURGERY.

DR. JOHN HOMANS, of Boston, reported

THREE HUNDRED AND EIGHTY-FOUR LAPAROTOMIES FOR VARIOUS DISEASES.

His general method of operating is as follows: The sponges are prepared by soaking in 1–1000 corrosive sublimate solution; they are then wrung out dry by an ordinary wringing machine; they are then kept in a 1–20 carbolic solution. The carbolic acid spray is always used, although it is considered unnecessary. An electric light is always kept in readiness.

Of the first five unantiseptic operations all the patients died. Of the antiseptic operations, 248 recovered and 34 have died. The vitality or viability of the patient has much to do with the result of the operation. The usual causes of death have been peritonitis or septicæmia. He was sceptical about the occurrence of mechanical intestinal obstruction, except as the intestines are paralyzed by peritonitis. Two cases in which the bladder was wounded during ovariotomy, recovered, and are living two and six years respectively after operation. In both cases the opening in the bladder was closed with silk sutures. Of the recoveries, nine patients died of abdominal cancer, a few months or years after recovery, and thirty have ventral hernia. There were fifteen children born to eleven women out of about two hundred heard from. The sexes do not correspond to the ovary remaining.

The usual length of his incision is about two inches. The stump is always tied, burned, and dropped back. Silk sutures are used, and care is taken to include all the abdominal parietes, particularly the transversalis fascia. Drainage was used in fifteen cases. The greatest number of consecutive recoveries after ovariotomy has been thirty-eight. The author had seen a suppurating ovarian cyst but once, and in that case the cyst had been tapped. There are cysts which contain fat and sebaceous matter, which to the naked eye looks exactly like laudable pus, and can only be distinguished from it by microscopical examination. There were two cases of swelling of the parotid gland after ovariotomy. Both recovered quickly, and he did not regard enlarge-

ment of the parotid during convalescence as of special importance.

DR. J. M. MATHEWS, of Louisville, Ky., in a paper entitled

WHEN IS COLOTOMY JUSTIFIABLE?

presented the following conclusions:

1. Colotomy is not justifiable in cases of cancer of the rectum. 2. In stricture or obstruction of the rectum, from whatever cause, within three and a half inches of the sphincter, colotomy should not be done. 3. The operation is not warranted in cases of ulceration of the rectum, unless of specific origin and accompanied with stricture beyond the reach of the finger. 4. Colotomy should not be performed for the presence of a tumor or aneurism causing pressure on the bowel. 5. In cases of congenital occlusion of the rectum, the operation is not to be recommended. 6. In cases where the operation is looked upon as a *dernier ressort*, colotomy should not be done, save for total obstruction, of benign or specific origin, located further than three and a half inches above the sphincter. 7. Where the rectum or sigmoid flexure is closed by a stricture of benign or specific origin, colotomy is indicated.

The reasons for advising against colotomy in the cases given above were: first, that the operation does not prolong life; second, admitting that life could be prolonged, the operation is not advisable; third, instead of prolonging life, surgical interference shortens life; and fourth, the pain is not materially lessened by the operation. Where the disease is located within three and a half inches of the sphincter, it may be treated by division. In other cases rectotomy is recommended.

DR. W. W. DAWSON, of Cincinnati, thought that there are cases in which colotomy seems to be indicated. He had now a patient of seventeen with an immense cancerous mass in the rectum, almost beyond the reach of the finger, and narrowing the calibre of the bowel to half an inch. There is, however, not the slightest sign of cachexia; the growth is accompanied by extreme pain. He had almost decided to open the abdomen, and, if possible, remove the mass with a portion of the gut. This operation has been done in Europe, but it is not old enough to enable us to judge of the results to be obtained. In syphilitic cases, where there is stricture, the stricture disappears under antisyphilitic treatment.

DR. SAMUEL BENTON, of London, understood the author to say that colotomy is not to be recommended for total obstruction due to cancer of the rectum. In his practice, if he can get beyond the cancer, he extirpates. If the growth is so high that he cannot remove the whole of it, he performs colotomy. He would recommend colotomy in these cases of cancer of the rectum. In the cases that he has seen life has been prolonged about fifteen months after colotomy. The last case lived eighteen months. There was complete obstruction, and if the operation had not been performed the patient would have died in two weeks. It is his experience that the straining and bearing-down at stool is relieved by colotomy. The growth, to a certain extent, remains at a stand-still, and a considerable amount of the pain is relieved. After rectotomy the stricture quickly returns. He treats benign tumors by electrolysis. This quickly relieves the stricture. This treatment is safe, and can be continued while the patient remains at his ordinary work. The stricture may return, but it can be kept down by a repetition of the electrolysis, or by dilatation practised by the patient.

DR. J. W. C. O'NEIL, of Gettysburg, thought that the proper course to be pursued in the case referred to by Dr. Dawson would be to put the patient under chloroform, inject the mass with carbolic acid and scrape it out. This will afford relief.

DR. J. W. HAMILTON, of Columbus, uttered a sound of warning against carbolic acid in the treatment of diseases of the rectum. The use of this agent is fraught with danger. Where there is obstruction due to cancer of the rectum colotomy should be performed.

DR. E. M. MOORE, of Rochester, said that it is extremely rare to have cancer at the age of seventeen, but sarcoma is very common. This is not accompanied by the cancerous cachexia, and every surgical operation for sarcoma is a failure. He would recommend colotomy.

DR. W. H. HINGSTON, of Montreal, said that the operation of colotomy should be performed where there is obstruction. It also relieves pain. When the whole of the mass can be gotten away, rectotomy should be performed.

DR. J. W. C. O'NEIL, of Gettysburg, had used carbolic acid for ten or fifteen years and as a general rule had found it of value.

DR. MATHEWS believed that carbolic acid was a hazardous remedy and has led to hundreds of deaths.

DR. DONALD MACLEAN, of Detroit, reported

THREE CASES OF LAPARO-NEPHROTOMY.

CASE I.—Mrs. A., aged twenty-five years, presented herself with what had been diagnosticated as an ovarian tumor. There was a cystic abdominal tumor about the size of the uterus at the seventh or eighth month of pregnancy. There was no history of renal trouble and no evidence that the tumor was connected with the kidney. The patient insisted that it had begun to grow from below. The operation was done with the expectation of removing an ovarian tumor. The left ovary was found enlarged to the size of a goose-egg and was removed. The large tumor was found to arise from the kidney, and it was removed. The patient did well for a time, but suppuration, with the formation of a fecal fistula, occurred. The patient finally made a perfect recovery.

CASE II.—Mrs. T., aged forty years, presented herself with a tumor of the left side of the abdomen which had been discovered six years previously. The enlargement had gradually increased. The tumor when first seen was too high for the ovary and too low for the spleen. The urine was normal. A diagnosis of tumor of the left kidney was made. It was decided to adopt the transperitoneal method of operating. A large cyst of the kidney was found. During removal it ruptured with the escape of a material like soft soap. The posterior layer of the peritoneum was brought together with sutures. The case did well until the eleventh day, when the temperature went up until it reached 104°. Examination showed fluctuation in the lumbar region. An opening was made with the escape of a large quantity of pus. Symptoms of collapse followed this operation, but these were overcome and the patient made a gradual recovery.

CASE III.—A female infant, twenty-two months old.

The family history was good. There was a tumor in the right hypochondriac region. This was movable and free from tenderness and pain. Tumor of kidney was diagnosticated and removal recommended. The incision was made just external to the rectus muscle. No difficulty was experienced and the operation was completed in seven minutes. The posterior layer of the peritoneum was closed with catgut sutures. For several days the case progressed favorably, but the temperature remained high. On the fifth day a careful examination was made to determine the cause of the elevated temperature. During the examination the child coughed and the abdominal incision gave way, allowing the intestines to escape. These were replaced and a search failed to show the source of the trouble. The wound was reunited. The temperature continued high and the child died on the ninth day. At the autopsy the posterior layer of the peritoneum was found united and in the space occupied by the tumor a small collection of pus was found surrounding the ligature on the pedicle of the tumor.

Dr. Maclean said that while the lumbar operation might be the safer there were cases in which the transperitoneal operation was preferable. These cases point to the necessity of efficient drainage although antiseptic precautions are adopted.

MILITARY SURGERY.

DR. JOHN ANDERSON, of London, read a paper on

HEATSTROKE IN INDIA.

DR. MARSTON, of London, in the discussion which followed, dwelt on the difference between heat-exhaustion, sunstroke, and heat-apoplexy. He related some of his experience in India and Egypt, and called especial attention to the sequelæ of these affections, among which he enumerated abnormal and erratic temperaments, insomnia, loss of "nerve," neuralgic headaches, neuralgias generally, and occasionally, though rarely, short attacks of mania. Sometimes the nerves of special sense are affected. Although motor paralyses do occur, they are rare compared with the other forms of nerve lesion. He dwelt on the importance of using a neutral and soluble form of quinine for hypodermatic injection, as tetanus is very liable to occur after slight punctured wounds in hot climates.

DR. LLOYD, of England, considered the prophylaxis and urged the importance of temperate living, good ventilation, and a strict observance of the laws of hygiene generally. Heatstroke, he said, is not ordinarily frequent in the British Navy; ninety per cent. of the cases occur in the Red Sea, and are mainly limited to a class comprised of bakers, cooks, saloon stewards, and stokers. The mode of living is likely the predisposing cause.

DR. SHERWOOD spoke of some of the sequelæ of sunstroke that came to the notice of the Pension Bureau of Washington. He said that cardiac debility and various neuroses, as epilepsy, neuralgia, headaches, etc., are common, and are causes which constitute disability.

DR. ELI A. WOOD, of Pittsburg, said that the exalted temperature of thermic fever is the only pathological condition worth considering in the treatment of heatstroke, and that the sequelæ would surely follow if the abnormal temperature was not reduced within a very short time to near the normal. He held that if the temperature was reduced, all the other symptoms would speedily disappear. Those cases occurring in this latitude are also much benefited if, in addition to the external application of cold, they be given a single hypodermatic injection of 15 grains of antifebrin.

DR. MAX J. STERN, of Philadelphia, remarked that some cases of thermic fever with marked pyrexia were speedily and permanently benefited by bloodletting.

DR. ANDERSON concluded by saying that in no sense did he wish to imply that reduction of temperature is the only one thing to be done in the treatment of these cases, and that external cold and antipyretics are the approved agents for that purpose. In the few cases he could speak of in which bloodletting had been employed death was the inevitable result.

DR. ROBERT REYBURN, of Washington, read a paper entitled

ARE WOUNDS FROM EXPLOSIVE BALLS OF SUCH A CHARACTER AS TO JUSTIFY INTERNATIONAL LAWS AGAINST THEIR USE?

The chief endeavor in the battles of ancient times was to kill as many of the enemy as possible in a given time. The same end is attained in modern battles, but it has been found that an enemy wounded sufficiently to become *hors du combat* is practically much more a source of weakness to his comrades than if he were slain in battle. It is probably too low an estimate to state that every wounded man needs the services of two able-bodied men for his care and sustenance until he becomes again fit for military duty. If, then, the object of modern war is not the taking of life, but rather the disabling and rendering unfit for active service of the enemy's soldiers, why should the inevitable horrors of war be further aggravated? The use of explosive balls does not accomplish any more effectually the disabling of the combatants, but converts slight wounds into grave and fatal injuries of vital organs. The characteristics of wounds caused by explosive balls or bullets are great shattering of the bones at point of injury, with comminution of the fragments, the soft tissues are extensively lacerated, with great destruction of the parts; this is followed by extensive sloughing. In many cases the reparative powers of nature are insufficient to fill up such extensive loss of tissues. The injuries are often accompanied by the dangers of both primary and secondary hemorrhage, and are also followed by the frequent occurrence of erysipelas and pyæmia. For these reasons, and for the sake of common humanity, we believe that the use of explosive balls or bullets in war should be forever prohibited by international law.

DR. CHARLES HOBART VOORHESS followed, with a paper entitled

ARE WOUNDS FROM EXPLOSIVE BALLS SUCH AS JUSTIFY INTERNATIONAL LAWS AGAINST THEIR USE IN WARFARE?

The object of wounding in warfare, he said, is to disable. It is most humane and effective simply to wound and not permanently disable. To kill a soldier disables only one man, but simply to wound one man takes away three, because two are required to carry him to the rear. He suggested the calling of an International

Medical Congress to protest against the present methods of destructive warfare, and offered the following resolution:

"*Resolved*, That, in accordance with the sense of this Section, the Secretary be instructed to present this opinion to the Ninth International Medical Congress, and ask that the Congress direct that the expression of their opinion on the subject of international laws against the use of explosive bullets in warfare, be forwarded to the President and Secretary of State of the United States, and to each representative of the Foreign Legation at Washington, with a request that each shall transmit the same to his respective Government."

DR. JEFFREY A. MARSTON, of England, did not know of the use of explosive balls in warfare, though they are used by sportsmen in tiger shooting, and in hunting other large game. Balls exploding in the air, such as shells and Shrapnel shot, were necessary to render as many members of an advancing column as possible *hors de combat*, and he did not see the necessity for the resolution.

THE PRESIDENT, DR. HENRY H. SMITH, explained that the object of the motion was to give the United States an opportunity to place herself in the rank of the humane nations.

The resolution was then carried *nem. con.*

DR. JEFFREY A. MARSTON, of the British Army, then read a paper on

AGE AND ACCLIMATIZATION OF SOLDIERS IN REFERENCE TO SERVICE.

He held that men make the best soldiers between the ages of twenty-five and thirty-five years; that while young men are better able to make great sudden exertions or undergo such strain, older men have greater powers of endurance. Short-term men suffer more with sickness than those who have been long in service. This is especially true of enteric fever, and the statistical returns to the English Office are so monotonous in their uniformity in this regard that it may almost be considered a general law that length of service lessens the liability to enteric fever. The time for gaining comparative immunity from this affection is about two years, and continued service gives almost absolute immunity.

DR. MORSE K. TAYLOR, U. S. Army, said that the heart is the first organ to fail after the first two years. In this respect his observations of our soldiers agree with the author's investigations of English soldiers.

OBSTETRICS.

DR. JAMES C. CAMERON, of Montreal, opened the session with a paper on

THE INFLUENCE OF LEUKÆMIA UPON PREGNANCY AND LABOR.

Our knowledge of leukæmia is fragmentary and incomplete, especially in regard to its influence upon the sexual and reproductive functions of women, and the broader question of heredity. We find it stated that sometimes menstrual and sexual disturbances are among its early prodromata—that it is most frequent at the climacteric—that in a few cases it has developed during pregnancy, or after several miscarriages or difficult labors, or after the sudden suppression of the menses from cold; that in the non-pregnant, amenorrhœa is the rule, though menorrhagia has been observed, and that uterine hemorrhage is rare. By a careful search through the literature of the subject, he had found reports of four cases in which leukæmia was alleged to have occurred during the course of pregnancy, but none where a woman already leukæmic has been known to have become pregnant. One case reported by Dr. Ingle to the Cambridge Medical Society in 1881, was rather a case of exaggerated leucocytosis of pregnancy than one of true leukæmia. Three other cases were reported to the Edinburgh Medico-Chirurgical Society in 1870, by Dr. Robert Paterson, but as a blood count was not made, and no autopsy held in the two fatal cases, their value is seriously impaired.

The case he reported is unique, as far as he had been able to ascertain, and possesses some points of unusual interest.

1. *Family history.* Grandmother, mother, and probably brother, have suffered from symptoms pointing to leukæmia. Two of her own children have had well-marked leukæmia, another is now in ill health with diminished red corpuscles and enlarged spleen. None of her children reach the standard of 5,000,000 red corpuscles per c.mm. Has leukæmia in this case been hereditary?

2. *Splenic tumor* was first noticed by the patient at the *beginning* of her sixth pregnancy.

3. *Spleen and liver* always enlarge during pregnancy and become tender.

4. Progressive enormous increase of white corpuscles, together with decrease of red corpuscles as pregnancy goes on.

5. *Absence of uterine hemorrhage* during labor and the puerperal period; labor was dry and bloodless, and lochia untinged with red.

6. Rapid subsidence of œdema and dyspnœa after the termination of labor, together with the rapid increase of red, and decrease of white cells.

7. Thoroughness of recovery, so as to be able to work; and the remarkably chronic course of the disease.

8. Recurrence of pregnancy—now the third time since splenic enlargement was noticed.

9. Remarkable difference between blood of mother and child, and between the blood in sinuses, vein and artery in the placenta.

10. Disastrous effect of nursing upon the child—causing purpura, vomiting, purging, and death.

DR. C. W. EARLE, of Chicago, referred to the operation of cirrhosis of the pancreas, as an etiological factor in the leukæmia of pregnancy.

MM. CHARPENTIER and BUTTE presented a paper on

EXPERIMENTAL URÆMIA; ITS INFLUENCE ON THE VITALITY OF THE FŒTUS.

They described a series of experiments upon pregnant rabbits to which urea was given in (1) doses large enough to prove rapidly fatal; (2) in daily doses of thirty grains or one drachm for a period of eight or ten days. The conclusions reached from these experiments were, that the fœtus was killed with the mother. The cause of the death of the fœtus was not the sudden diminution of blood pressure in the maternal circulation, as held by Runge, nor the diminution in the oxygen of the maternal blood, but a direct fatal intoxication of the fœtus by maternal blood surcharged with

urea. The views suggested by the experiments, the authors claim, are confirmed by their clinical observation.

Prof. Lusk, of New York, remarked that formerly he was of the opinion that the fœtus died of asphyxia —accumulation of carbonic acid in the blood—but owing to the researches of Charpentier and others, it was necessary to add the factor of direct poisoning by urea, and other retained excrementitious urinary products.

Dr. Duncan C. McCallum, of Montreal, thought Charpentier's paper an argument for the induction of premature labor in the interest of the child, as well as of the mother, in cases of morbus Brightii during pregnancy.

Dr. Sänger, of Leipsic, then opened a discussion

ON THE CÆSAREAN SECTION.

The good results obtained by the Porro operation, he said, put forawhile Cæsarean section in the background. With the use of antiseptic precautions, and with some improvement in the performance of the operation, such good results have been obtained by the Cæsarean section, that this operation is now preferable to Porro's in the following cases: 1st. When the child is living, and cannot be delivered alive by any other operation, as by application of forceps, turning, or the induction of premature labor. 2d. When the child is dead, and cannot be delivered by craniotomy or embryotomy, or only be delivered with the greatest danger to the mother. But good results can be obtained by Cæsarean section only under certain conditions, and when the operation is performed according to new and approved technical principles.

The conditions required for a successful performance of Cæsarean section are, (*a*) absence of septic infection in the uterus; (*b*) early performance of the operation; and he thinks that the reason why American physicians have not obtained the same good results as he, is that they delayed the operation too long, or were not called upon to perform it until after other operations had been unsuccessfully tried.

In regard to the technique of the operation, he laid stress on the following points: The preparation for the operation, and the antiseptic precautions should be made as in case of laparotomy. In private practice, some of the measures could be simplified, but essentially they ought to be the same. The opening in the abdomen is made in the linea alba, but should correspond to the incision of the uterus. Therefore, the incision is made without regard to the navel, over the middle of the fundus toward the middle of the symphysis, extending about six and a quarter inches. It is not advisable to evert the unopened uterus, on account of the large incision required for this purpose, except in cases where the fœtus is dead, or there is not sufficient assistance. He also opposes the application of the elastic ligature before the uterus is opened, because the ligature endangers the life of the child, or may incarcerate parts of the child, so that the ligature must be loosened at a time when the hands of the operator are required for more important things. Beside this, the danger from hemorrhage is not so great as is commonly supposed, and can be easily diminished. He never everted the uterus *in toto*, nor applied the ligature before the incision of the uterus. He opens the uterus in situ by a frontal median incision; if he hits the placenta, he cuts through it or separates it on one side. The child is extracted by the legs, and if the head becomes incarcerated the incision is enlarged upward, to prevent a laceration of the wound downward. At the same time an assistant presses the abdominal walls to the uterus, to prevent prolapse of the intestines, and the flow of fluid into the abdominal cavity. By pressing on the inferior segment, and by a slight torsion or flexion of the uterus and of the broad ligaments, the hemorrhage can be lessened. There is some danger in the removal of the elastic ligature, and he advises to do without it if possible.

In regard to the application of sutures, he drew attention to three points, which are considered as the most important: 1. Accurate union of the incised surface of the uterus by numerous sutures, whereby a broad and close union is obtained. 2. Avoidance of suture canals in the cavum uteri. 3. Especial union of uterine surfaces instead of the serosa uteri. As suture material, he prefers silk to silver wire, because silk can be absorbed. Lately, excellent results have been obtained with catgut prepared in oil of juniper, or chromic acid, or sublimate.

Sänger gives the following indication for the Porro operation when the flow of secretion of the uterus is impeded by stenosis of the cervix or vagina, or by tumors, and in cases of infection of the corpus uteri. But he prefers Cæsarean section when the myomata are retrocervical or retrovaginal, because the removal of the whole mass, under the circumstances, is impossible, or very dangerous, and to remove the uterus alone has no result of value.

In cases of osteomalacia he prefers the Cæsarean section, with removal of the ovaries, to the Porro operation. He takes exception to A. Martin's recommendation to perform the Porro operation in cases in which the puerperium becomes dangerous to the woman, as in cases of far advanced affections of the heart or lungs. He thinks that a woman in such a case has as good a chance of recovery after Cæsarean section as after the Porro operation.

GYNECOLOGY.

Both morning and afternoon sessions were devoted entirely to the reading of papers, discussion being postponed until a subsequent occasion.

The morning session was opened by a paper which was sent by Dr. H. R. Bigelow, of Washington, the subject being

CONSERVATIVE GYNECOLOGY.

His idea was that surgery is conservative when it tends to alleviate suffering without depriving the human frame of any of its component elements. Conservative gynecology was defined as any plan which tends to preserve the just equilibrium of human energy in this specialty, before resorting to means for the elimination of the offending organ. It is thus opposed, in a certain sense, to surgical gynecology in which the too free use of operatives measures constitutes a dangerous tendency. It was not believed to be sufficient that a gynecologist be well informed as to the anatomy and physiology of his particular department; it was obvious enough that he should be well equipped in general medicine. This

notwithstanding the fact that few medicines are of use in diseases which are peculiar in gynecology.

Alluding to the subject of fibroid tumors of the uterus, he called attention to the good results which had been obtained by systematic treatment with ergot, and formulated his belief as to the proper treatment of such growths as follows:

1. Many remarkable cures of submucous uterine fibroid tumors from the use of ergot are collected, which is ample reason that this subject should receive careful attention. 2. Electricity is also a remedial agent of great value for these neoplasms. 3. The use of tonics, aperients, and suitable hygienic measures should be properly systematized. 4. Cutter's diet treatment should receive careful investigation. 5. Early operations for these growths are only exceptionally required. 6. Dangerous hemorrhage from them is not the rule. 7. The percentage of these tumors in which life is endangered by hemorrhage is small. 8. An operation should only be the last resort. 9. Hysterectomy, myomotomy, and oöphorectomy will always be dangerous operations, and their dangers should be clearly pointed out to patients.

Conservative gynecology is entirely applicable to tubal diseases and inflammations of the ovary. Oöphorectomy for epilepsy, *per se*, can hardly be conceived to be of advantage by any logical process. Operations for the relief of dysmenorrhœa are seldom indicated.

DR. WEEKS, of Portland, Maine, presented a paper entitled

PREGNANCY COMPLICATED BY UTERINE FIBROID TUMORS.

The paper was based upon a case in which this grave complication existed, and in which the author's preference was to wait until term and then perform Cæsarean section. His opinion was overruled, however, and he was obliged, in deference to the opinion of several distinguished colleagues, to induce premature labor at the fifth month. He succeeded in delivering the fœtus after decapitation, but the mother did not rally from the shock of the operation.

Of thirteen distinguished gynecologists whose opinions upon this subject were obtained by correspondence, nine were in favor of premature labor. To this opinion the author dissented, believing that the best results must usually be obtained by allowing the gestation to continue to term, and then performing Cæsarean section, removing the ovaries and tubes at the same time if possible.

DR. GRAILY HEWITT thought that failure in the author's case might have been due to too rapid evacuation of the uterus. In such cases labor should proceed very slowly.

DR. TRENHOLME, of Montreal, narrated three cases in his experience in which gestation was complicated by the presence of uterine myomata, all of which resulted favorably for the patients. He believed that women with such tumors should not despair of becoming impregnated, and that in very many cases they might with safety go to term.

DR. LAWRENCE, of Bristol, England, observed that the question had arisen as to the propriety of marriage for women who were known to have fibroid tumors of the uterus. His opinion was, that marriage was proper if the woman were not suffering from the symptomatic effects of the tumor. He had seen eight cases in which pregnancy was complicated by such tumors, and in several of them the effect of the pregnancy was to dispose of the tumors. He thought that premature labor should not be induced if there were any reasonable prospect that there would be a normal termination.

DR. GORDON closed the discussion (in the absence of Dr. Weeks), expressing his opinion that premature labor in the author's case was not the proper procedure. He agreed with Dr. Hewitt, that if labor were induced in such cases, it should proceed very slowly. The position of the fibroid should be influential in deciding as to the method of procedure. If the tumor were in the cervix, and likely to fill the pelvis and occlude the parturient passage, prematurely induced labor would usually be indicated.

DR. DANIEL T. NELSON, of Chicago, presented a paper on

THE TREATMENT OF UTERINE MYOMA WITH ERGOT.

It was shown that the influence of this drug upon hypertrophied muscular fibre was much more intense than upon normal. Hence, also its influence must be much more positive upon a diseased (*i. e.*, hypertrophied) uterus than upon a normal one. Its influence must also depend upon the position and surroundings of the tumor, with respect to the mechanical advantage to be gained. Its use by suppository or subcutaneously was often possible when it would not be tolerated for a long time by the mouth. Collective investigation upon this subject should receive earnest attention. The conclusions were:

1. The cases upon record show conclusively the value of this method of treatment.

2. Hyperæmia of the uterus whether induced by miscarriages, displacements, or other abnormal conditions predisposes to the development of these neoplasms.

3. A probable additional cause is some nervous disorder of a trophic character.

4. Ergot is not indicated if the tumor is subperitoneal and adherent to surrounding viscera.

5. Gangrene, from the prolonged use of ergot, is not likely to occur.

DR. BOZEMAN criticised the author's statement that fibroid tumor of the uterus is infrequent in black women. His experience, and that of many other gynecologists, was that black women are much more susceptible to such conditions than white women. On the other hand, ovarian tumors in black women are rarely seen.

DR. NELSON, in closing, said that no one had offered any suggestion which had convinced him of the superiority of any medicinal agent to ergot in the treatment of fibroid tumors of the uterus.

DR. APOSTOLI, of France, read his paper entitled

FARADISM IN GYNECOLOGY.

The value of the induced current as a therapeutic agent was enunciated, and reference made to the author's extensive experience for the past few years in this direction. The coils and electrodes devised and used by the author were exhibited, and the method of using them described.

The author's system of treatment was also explained

at length in English by Dr. Smith, of Montreal, recently a student with Apostoli, subsequent to the reading of the paper.

DR. SMITH, of Montreal, read a paper upon

A NEW THEORY OF TREATING UTERINE DISEASE AND DISPLACEMENTS BY ELECTRICITY.

This theory consisted essentially in the use of electricity after Apostoli's method. The principal cause of uterine disease was said to be want of muscular tone; restore this tone, relieving thereby the organ of its superfluous blood, especially venous blood; improve also its nervous apparatus, and the disease would disappear.

The great value of the electric current in relieving pain in the pelvic organs was also a matter of personal observation by the author.

DR. F. H. MARTIN, of Chicago, read a paper on

THE ELECTROLYTIC TREATMENT OF UTERINE MYOMA,

based upon Apostoli's method of treatment. One of the chief elements of value consisted in exactness of dosage, which is now rendered possible by the use of the milliampèremeter. The factors in this plan of treatment are

1. The local effect of the pole; acid effects being obtained at the positive, and alkaline at the negative pole. Density, rather than volume, is the efficient means; hence arises the method of treating hemorrhage in connection with these tumors.

2. The atrophic effect of the current; it is not the electrolytic action alone which produces the desired end.

3. The electrolytic action of the current. The combined elements being separated, absorption is favored.

4. The antineural effect of the current.

The electrodes used by the author were exhibited and described. For the external pole, an ingeniously constructed hollow disk covered with membrane is used, which, being filled with water and placed upon the abdomen, diminishes to a great degree the resistance of the skin.

No galvanopuncture is used, as done in Apostoli's method, an electrolytic effect, and not a caustic being alone required. A current of more than 100 milliampères is never used. The advantages of this method are: 1. It is free from danger. 2. It is painless. 3. It checks hemorrhage. 4. It rapidly reduces the size of the tumors. 5. It stops neuralgia. 6. It admits of exactness of dosage.

The papers of Drs. Cutter and Semeleder upon the same subject as the foregoing were referred to by the Chair. They will appear in the published Proceedings of the Congress.

DR. ALFRED C. GARRATT, of Boston, read a paper upon

THE TREATMENT OF TUMORS OF THE BREAST BY ELECTROLYSIS.

A prime necessity was that the tumor should be seen in its early stage—whatever its character. Under such a condition women should be encouraged to believe that they could be radically cured. Broad and soft electrodes were used by the author, the entire surface over the tumor being submitted to the action of the current. Each séance should last twenty to thirty minutes, and the current should not exceed 5 to 50 milliampères, according to the resistance. The applications might be made every day or every other day. In some cases only three to four applications were necessary, in others twenty to thirty. The interrupted current might be used for a few minutes after having used the primary. The author had treated 180 cases of mammary tumor by this method, and in 157 there had been a cure, with no recurrence, so far as he knew, in a single case.

DR. ALEXANDER DUNLAP, of Springfield, Ohio, read a most interesting paper on

EARLY EXPERIENCE IN OVARIOTOMY.

His first operation was done in 1843 amid great difficulties and opposition, at the earnest request of the patient, who was conscious and intensely interested during the entire procedure. She lived for twenty days and then succumbed to kidney disease.

The paper was largely reminiscent and showed the great obstacles which were experienced by the author and his fellow pioneers.

DR. GILMAN KIMBALL, of Lowell, also gave interesting personal reminiscences, chiefly showing the hostility of the profession to ovariotomy and ovariotomists a generation ago.

DR. CORDES, of Geneva, Switzerland, presented a paper entitled

MEDICAL TREATMENT OF UTERINE CANCER.

This method of treatment was considered applicable only to those cases in which radical operation was inexpedient or impossible. It is a well-known fact that many cases in which palliative treatment alone is used survive a long time, perhaps as long as if operative measures had been adopted. Among the substances which may be used topically are solutions of sulphate of copper, sulphate of iron, bromine, acetic acid, iodized glycerine, pepsin, and papaine. The author gave the preference, however, to terebene which he is in the habit of applying on cotton-wool every two or three days. His results with such applications have been very satisfactory.

DR. ERNEST CUSHING, of Boston, concluded the afternoon's work with a paper entitled

MALIGNANT DEGENERATION OF GLANDULAR HYPERPLASIA OF THE UTERUS.

He dissented from the commonly received views of Ruge and Veit, and Thiersch and Waldeyer, respecting the invariable epithelial origin of cancer. The unexplained part of their theory was the frequent appearance of accumulations of small, round cells with epithelial cells in the so-called transition stage, which the author had found did not terminate in many cases in cancer. Another theory must, therefore, be substituted for that of epithelial irritation, as a primary or potent cause, and the author was inclined to believe that it came from without, and, reasoning from analogy, was of an infectious nature. The more frequent use of the cautery was suggested in the treatment of cancerous growths, on account of its antiseptic influence.

The paper was followed by the projection upon an illuminated screen of a large number of photographs from microscopical sections made by the author in the

investigation of this subject, in which the difficulty of absolutely determining the existence of cancer in its earliest stage was amply shown.

Wednesday, September 7th.

General Session.

The Congress came to order at the call of the President, at 10 A M.

The Chairman of the Committee of Arrangements, Dr. A. Y. P. Garnett, announced that some misapprehension had occurred with regard to the reception at Grass Lands, the country residence of Secretary Whitney, that evening. This invitation had been restricted to those only whose presence was desired, as indicated by the receipt of special cards of invitation which had been issued. He further stated that tickets to the reception to-morrow night, at the Pension Office, had gotten into the hands of persons who do not belong to the Congress, and "in order to prevent the humiliating spectacle of Monday," presented at the conversazione, all invitation tickets would be cancelled, and delegates, who were requested to wear their badges, would be presented with new and proper tickets upon calling at the office of Albaugh's Theatre. He also said that, "in order to prevent foreign members being engulfed in the mob, as they were last night, at the President's reception," a special entrance has been arranged for them to-morrow evening.

Dr. N. S. Davis stated that as a special committee had been appointed at Copenhagen to consider and report at this meeting on the Collective Investigation of Disease, this committee (if any of them are present) would meet at the Riggs House in the afternoon.

The President repeated his announcement of yesterday, that the programme had been changed, so as to provide for the reading of but one address at each general session, in order not to interfere with the morning meetings of the Sections. He further announced that Dr. Neudörfer, of Vienna, and Dr. Lutaud, of Paris, who were to read general addresses, would be absent from the Congress, but no reason was assigned for their failure to appear.

The President then vacated the Chair in favor of Dr. Durante, of Italy, and Prof. Semmola delivered in French his address on

bacteriology and its therapeutical relations.

(See page 298.

At the conclusion of the address, Dr. Louis A. Sayre, of New York, said he was sure that all the members of the Congress had, like himself, been electrified and delighted as they listened to the eloquent address of Semmola. His masterly exposition of the important subject of bacteriology and its relations to therapeutics, and its wonderful influence upon the future of medicine, placed them under a weighty debt of obligation. He moved a unanimous vote of thanks.

Dr. Hingston, of Canada, seconded the motion in a few complimentary remarks, part in French, and part in English.

Dr. A. L. Gihon offered a resolution that the President of the Congress be authorized to appoint a committee, to consist of an equal number from each nationality represented in the Congress, for the purpose of selecting the place of meeting of the Tenth International Medical Congress to be held in the year 1890, which committee shall report on Friday morning, immediately before the address of Dr. Blandford. Adopted,

The session then adjourned.

SECTIONS.

Public Medicine.

The President read a paper forwarded by Dr. Benjamin W. Richardson, of London, on

some points in the growth of preventive medicine in great britain.

Dr. Richardson called attention to the fact that the English people being cut off from other countries by the sea, had to invent all measures of prevention for themselves; and yet this very isolation did good in the end, owing to the fact that it made England mistress of the seas, and by so doing necessarily produced conditions favorable to the study of public health, owing to the large number of men under control. England stands equal to any nation in the practice of preventive medicine. The necessity of preventive measures was illustrated by percentages showing the relative death-rate in the army, from disease and war in former years, as compared to that of the present day. In older times the death-rate from disease far exceeded the death-rate from injuries, but this condition of affairs has been almost reversed at the present day. Every war England has had has taught her a lesson in preventive medicine, and while the medicine has often been a bitter one, it has in the end proved of value. In the Crimean conflict measures for sanitation were carried out which had previously existed here in theory, while many other conditions arose which required urgently the entire attention of all persons interested in public medicine.

He also spoke of the changes produced in public institutions, such as prisons and workhouses, by the sanitary measures lately introduced, and of the decreased death-rate among the laboring classes by the same.

Dr. Joseph Jones spoke of the valuable information which the Civil War had given us in regard to these matters, and regretted that while the Federal army had been able to use its information by reason of the support of the Government, that the Confederate lessons had unfortunately almost perished, owing to want of proper care and support.

Dr. Y. R. LeMonnier, of New Orleans, read, in part, a translation of a paper forwarded by Dr. Domingos Freire, of Rio de Janeiro, Brazil.

the inoculation of yellow fever.

The author first narrated, as briefly as possible, the history of his discovery and announcement of the microörganism of yellow fever. Ever since 1880, he had labored to establish the identity as well as to produce an attenuated form of the virus of the disease which could be employed for the purpose of preventive vaccination. In addition to his first report he has published nine memoirs on the subject.

The microbe, he said, is an infinitesimally small vegetable organism, found in the blood as well as in the

secretions of the yellow fever patients. Its natural history is as yet very obscure. Science is as yet but lisping the first syllables concerning it. Observers have thus far pursued purely technical methods of study, without giving sufficient attention to the physical character, the mode of life, and the chemistry of the organism. This carelessness on their part has been to blame for many failures in the study of not only this but of all micro-organisms.

In the concluding portion, the author gave the statistics of his vaccinations in Brazil. He showed that the vaccinations, sanctioned by the government, had been made during a severe epidemic of the disease, in the worst quarter of the city, among persons, for the most part foreigners, and therefore more susceptible to the disease, living in a condition of wretchedness hardly conceivable in a foreign country. The result had been that, with almost no exceptions (the exact figures were given) those who were vaccinated escaped the disease, although they remained exposed to the contagion, whereas those who were unvaccinated died in vast numbers. In conclusion he asked attention to a number of monographs by himself and others on the subject in question.

[Dr. Freire's paper will appear in full in an early issue of THE MEDICAL NEWS.]

DR. J. MCF. GASTON was thoroughly convinced that the claims of Dr. Freire were honest, as he was stationed in Brazil during the first years in which the experiments were carried on, and was aware of their nature and the manner in which they were being received before he left that country. Further, he thought, it would not be possible for Dr. Freire to come so far away from home or even to publish so repeatedly his claims and the accounts of his investigations if they were not as he represented them, without giving occasion to his opponents at home to produce at least some evidences of the deception. In conclusion he proposed a series of resolutions which after amendment were adopted as follows:

Whereas, inoculation against yellow fever, if it prove successful after further examination, is clearly beneficial to the human race throughout the world, and

Whereas, the facts presented by the experiments of Dr. Freire afford reasonable assurance of its protective influence in Rio de Janeiro,

Resolved, that this Section recommends coöperative investigation of the results obtained by yellow fever inoculation as protection against that disease, and that adequate preparations by the governments represented in this Congress be recommended, and that the matter be brought to the attention of the general sessions of the Congress.

DR. JOSEPH JONES, of New Orleans, President of the Section, stated that he had confirmed all of the statements of Dr. Freire with reference to the microbic origin of yellow fever, and that he had many years ago seen and described the microörganism referred to.

DR. EDWARD LEIGHTON, of London, then read a paper on

THE METROPOLITAN SYSTEM OF DEFENSE AGAINST INFECTIOUS DISEASES.

The paper consisted in a review of the workings of the system in question throughout the large cities of England and Scotland, resembling very closely that with which we are amiliar in the cities of the United States The essayist concluded with a strong endorsement of the system and its workings, although he pointed out some important features in which it was yet in a measure defective.

GYNECOLOGY.

DR. CUTTER, of New York, read a paper on

GALVANISM OF UTERINE FIBROIDS.

The first operation was performed, in conjunction with Dr. Kimball, of Lowell, upon a patient of the latter, August 21, 1871. Platinum needles were used, and the tumor was punctured from opposite sides of the body, the needles then being approximated. The author had no knowledge that any similar operation had ever been performed previous to that one. The platinum needles were found unsatisfactory, not being stiff enough to penetrate readily the firm tissues of fibroid tumors. The author then devised electrodes of steel, one variety being triangular in cross section, and another corkscrew-shaped and gold plated. The battery was a single cell with a large number of elements, and a current of sufficient intensity for any practical purpose was obtained with it. In the development of his method the author experienced great opposition and hostile criticism. Referring to the alleged value of the milliampèremeter, the author thought it was not absolutely essential, as his own experience had demonstrated that good results could be obtained without it. Apostoli's criticisms of the author's work and methods were probably made without due appreciation of the facts.

DR. SMITH, of Montreal, replying for Dr. Apostoli, observed that the latter did not have the author of the paper in his criticism upon the methods for treating uterine fibroid tumors with electricity, which preceded his own. Apostoli preferred to puncture the tumor through the vagina rather than through the abdominal wall on account of the greater safety of the former in case of subsequent inflammation. This method of puncture was also favored on the ground of greater accessibility in most cases. Apostoli's proposition was, that all varieties of uterine and ovarian disease, with the exception of ovarian cysts and malignant diseases, were amenable to treatment by one or the other form of electricity. With regard to the curability of fibroid tumors without galvano-puncture, Dr. Martin had stated in his paper see Tuesday's proceedings) that they could be cured. If a puncture were made, Apostoli recommended the use of a trocar, which should be plunged into the tumor (per vaginam) to a depth of one-third or one-fourth of an inch. Antiseptic precautions before and after the operation should be the invariable rule.

DR. F. H. MARTIN thought it should be remembered that the milliampèremeter merely indicated the strength of the current which was passing, not its density or the resistance which it was overcoming: it was, therefore, not so essential a factor in the appliances for treatment as Apostoli maintained. He criticised Apostoli's method of treating hemorrhage on account of the enormous strength of current which it required. He was able to accomplish the same end with the use of far less force by applying sounds successively to different sections of the uterine mucous membrane, each sound being insulated except for a very limited extent, which varied

as to situation sound, the electrical current passing only through the non-insulated portion. He believed that Cutter's battery was inefficient for the purpose for which it was constructed, and that it could by no means give rise to a current which would traverse a space of two inches, through solid tissues, as asserted.

Dr. Kimball, of Lowell, being asked by the Chair for a brief account of his early experience with electricity in the treatment of fibroid tumors of the uterus, said that he believed the idea of such a method of treatment was original with him. He had become tired of telling women with such tumors that nothing could be done for them, and the use of galvanism occurred to him as an expedient that might be serviceable. Dr. Cutter assisted him in carrying out his ideas and in operating upon certain patients.

Dr. Garratt, of Boston, referred to experiments which he had performed upon rabbits to test the strength, resistance, and effect of galvanic currents. He found that no great pain was caused in the animals by the introduction of his electrodes, but when the latter were approximated within the tissues, there were evidences of intense pain. He found that it was quite possible, as Dr. Cutter had stated, to pass a current through and across two inches of solid tissue. This seemed to be contrary to the fixed laws of electricity, and he could only account for it by believing that the resistance within the tissues of the body was far less than at the surface.

Dr. Apostoli closed the discussion of his paper (see Tuesday's proceedings) by reiterating his belief in the necessity of exactness of dosage in the administration of electricity and the value of the milliampèremeter for that purpose. Such a plan of dosage was insisted upon if the medicament, calomel, opium, etc., were used to accomplish certain ends, and the same rule should hold good in the use of electricity.

Dr. Cutter desired to ask if Dr. Apostoli had ever actually cured a woman with fibroid tumor of the uterus by his method.

Dr. Apostoli replied that he had seen relief from the symptoms which such patients complained of under his treatment; that is, the women were no longer sick.

Dr. M. D. Spanton, of Hanley, England, forwarded a paper on

CYSTITIS IN WOMEN,

which was read by the Secretary.

The author wished to draw the line sharply between irritability of the bladder and inflammation or cystitis. The former is a very common condition, and can be excited by the greatest variety of causes, whether constitutional or local. If the irritability thus excited by whatever cause, be prolonged sufficiently, cystitis will result. The author considered the empirical treatment of bladder troubles quite unjustifiable. The organ should first be carefully explored, its true condition, and, possibly, its cause ascertained, after which it should be treated symptomatically, each case upon its own merits.

Dr. Graily Hewitt read a paper upon the

RELATIONS BETWEEN CHANGES IN TISSUES AND CHANGES IN THE SHAPE OF THE UTERUS.

Whatever the statements of various investigators may be as to the condition of the uterus post-mortem, the author did not believe such statements could be taken as a basis for propositions concerning the position and condition of the tissues of that organ during life and health. The term chronic metritis is in common use, to signify a softened, possibly enlarged condition of the organ, with or without a more or less offensive discharge from its canal. This need not be an inflammatory condition, or the result of inflammation. It more frequently coexists with a weak and flabby condition of the tissues of the body in general; that is, a condition of general starvation. With this condition the organ is very susceptible to changes of position when slight causes, such as traumatism, etc., are superadded. Then congestion and actual inflammation may follow; a puerile condition of the uterus also predisposes to faults of position. Hence it may be said that undue softness of the uterus, with imperfect nutrition, precede flexions. These are followed by congestions and hypertrophy. Compression of the uterine tissues from flexion, is followed by chronic metritis and endometritis.

Dr. W. C. Wade, of Holly, Michigan, then read a paper upon

DISPLACEMENTS OF THE UTERUS.

His conclusions were the result of an experience of 3000 cases, and he believed that displacements were more frequent than any other form of female disease. His conclusions were thirty-nine in number, and demonstrated principally that such conditions were most amenable to treatment by mechanical appliances, and that every gynecologist to be successful should be possessed of sufficient ingenuity to prepare an instrument suited for each particular case.

Dr. William L. Reid, of Glasgow, Scotland, read a paper entitled

THE REMOTE RESULTS OF THE OPERATION OF SHORTENING THE ROUND LIGAMENTS FOR DISPLACEMENTS OF THE UTERUS.

He defined remote results as those which occurred at least one year after the performance of the operation. Among British gynecologists, from whom the author had made personal inquiries upon this subject, Matthews Duncan, Skene, Keith, Playfair, and Wallace could not speak well of it as the result of personal experience and observation; Halliday Croom approved of it; Alexander himself thought it would accomplish certain results if properly done; and Adams had found permanent improvement several years after the performance of the operation in certain cases. If the operation were not done carefully and thoroughly, it should not be blamed if good results did not follow. In the author's experience (eight cases) there was permanent benefit in some and not in others. It did not seem to follow that general improvement would necessarily result even though the original displacements of the uterus remained permanently relieved. If the perineum has been destroyed and a pessary cannot be used to remedy a displaced uterus, this operation is indicated. Immediate relief may not be obtained, and it may be necessary for a patient to be under observation for six months after the operation has been performed. If a pessary can be worn after the operation, the results may be better than would otherwise be the case.

(*To be continued.*)

NEWS ITEMS.

WASHINGTON.

(From our Special Correspondent.)

THE MEETING OF THE CONGRESS.

THE auditorium of even the handsomest theatre never presents a very cheerful or inspiriting appearance in the daytime. The lights are dim, the scenery, divested of the artificial glamor of the footlights, looks unreal, and there is a general flavor of "funeral baked meats" pervading the whole atmosphere. Albaugh's Opera House, in which the International Medical Congress assembled for its ninth triennial session, proved no exception to this rule, though the theatre is new and well constructed. The slanting rays of light which fell from the windows half opened on the eastern side of the building, and glanced upon the Egyptian sarcophagus-like decorations of chocolate and old gold, and half illuminated the strange mixture of gray heads and young faces which crowded the auditorium, leaving in comparative obscurity the brilliant array of ladies and their escorts who crowded the galleries, gave to the scene a weird and strange effect. The whole of the lower part of the theatre was given up to the delegates, and they more than filled its utmost capacity. In the boxes and the galleries were the spectators, some of whom were the ladies who had accompanied the delegates, but many were visitors attracted out of curiosity and by the announcement that the President of the United States would be present and open the proceedings.

Long before the time named for the opening every seat was filled, and those familiar with previous sessions of the Congress, glancing around on the members assembled, saw a number of physicians who occupy high positions in the profession, but they were, at the same time, struck by the notable absence of a very large proportion of those who are best known in American medicine. Among the New England representatives, the Bowditches, Bigelow, Warren, Cheever, Storer, White, Blake, and the well-known features of the Autocrat of the Breakfast Table, Dr. Oliver Wendell Holmes, were missed. New York had evidently failed to send Gaillard Thomas, Jacobi, Barker, Draper, Sands, Dalton, Weir, Loomis, Markoe, Emmet, Agnew, Janeway, Delafield, and Noyes. Among the Philadelphia delegates one looked in vain for Stillé, Hayes Agnew, Leidy, Da Costa, Gross, Weir Mitchell, Bartholow, Wood, Pepper, Parvin, Osler, Duhring, or Goodell; and from the South and West many prominent men were also missed, including Donaldson, Johnston, Tiffany, Welch, Atkinson, Hunter McGuire, Battey, Campbell, Whittaker, Reamy, Yandell, Kinloch, Conner, Reeve, Fenger, Geddings, Hardaway, Engelmann, Hyde, Lyman, Hosmer Johnson, and Byford. Amongst the foreign delegates the conspicuous absentees were equally marked, and on all hands were heard involuntary inquiries—where are Sir James Paget, Virchow, Jenner, Pasteur, Bryant, Verneuil, Gull, Volkmann, Lister, Jaccoud, Spencer Wells, Esmarch, Playfair, Ziemssen, Holmes, Charcot, Liebermeister, Mackenzie, Koch, and Erichsen? All these, and more, whose presence had graced, and whose labors had given dignity and importance to previous Congresses, were painfully missed.

Precisely at eleven o'clock the curtain rose upon a sylvan scene and disclosed the President of the United States seated in the woods at a small table, with the Secretary of State on his left and Speaker Carlisle on his right, who modestly endeavored to conceal his identity behind a very tall white hat. Grouped around them were some fourteen or fifteen members of the Executive Committee and distinguished foreigners, each one decorated with a little silver medal on a background of crimson ribbon. As the curtain rose, the audience greeted the Chief Magistrate with the heartiest applause.

The Chairman of the Executive Committee, DR. H. H. SMITH, of Philadelphia, stepped forward from the right wing and introduced the President of the United States, who was received with all the enthusiasm befitting the occasion. He rose promptly and opened the Congress in a few sonorous and well-delivered sentences, and on ending gave a sharp tap of the gavel on the table before him.

When the nominations for Vice-Presidents were subsequently read, embracing names eminent in medical science the world over, the suggestion involuntarily occurred to all that not a dozen were present of the entire list of nearly eighty distinguished foreigners upon whom it was proposed to confer this honor. This was so obvious that a delegate in the back part of the theatre, speaking with a strong Irish accent, said: "Mr. President, I would like to ask if it is proper to elect men as Vice-Presidents who are not present? I would move to amend"—— Here President Davis interposed and said: "It is hardly in order to interrupt the proceedings now, because it is impossible to know who will be here. The gentlemen who have been named have all been communicated with and have accepted the positions, and I declare them elected."

This cutting of the Gordian knot was received with due applause, but when President Davis sought to follow up his victory by inviting the Vice-Presidents to step upon the platform the force of the objection was apparent, as, after a painful pause, only one Vice-President, Dr. Phillips, of London, disclosed his presence. He made his way to the stage, and Dr. Davis hurriedly remarked that it was not necessary to delay the proceedings by waiting for the other gentlemen.

Secretary General Hamilton's report was brief and pointed, and noticeable chiefly for the cleverness with which it skated over the points of difference in New Orleans and Chicago, which had played so prominent a part in the fortunes of the Congress.

The address of welcome from the Secretary of State, Mr. Bayard, was scholarly and graceful.

The replies of the foreign delegates were the most interesting feature of the meeting. The first call made by President Davis upon the English Deputy Surgeon-General received no response. Dr. William H. Lloyd, of the Royal Navy, was then appealed to, and with some nervousness he gave response in unmistakable English accents. Dr. Léon Le Fort, portly, dignified, and gray-haired, responded briefly, on behalf of France, in his native tongue. Professor Unna, a dermatologist, selected to respond for Germany, replied in German. But the distinguished representative of Italy, Professor Semmola, whose appearance, graceful gestures, and artistic vocal inflexions, reminded many present of Léon Gambetta, answered in French, and with force

and fluency. The Russian representative, Professor Reyher, spoke briefly and quaintly in broken English.

The opening session ended with an inaugural address from Dr. Davis. During its delivery the galleries had emptied, and many had departed from the body of the meeting. At its close, President Cleveland, Secretary Bayard, and Speaker Carlisle successively shook President Davis by the hand, and the first day's proceedings were declared at an end.

An unpleasant episode occurred in connection with the responses of the foreign delegates which has created much talk. It appears that Prof. Durante, of Rome, was requested by the Secretary-General of the Congress to respond on behalf of the Italian members, and he accordingly prepared an address, and called upon Dr. Hamilton to inquire about the hour he would be expected to deliver it. Dr. Hamilton then informed him that Dr. Semmola, of Naples, would respond to Secretary Bayard, as he claimed the right, as a representative of the Government of Italy, and the Committee felt constrained to concede it to him. Within an hour Prof. Durante sent the following note to Dr. Hamilton :

Secretary-General of Medical Congress :

Having been invited by the Secretary-General of the Medical Congress, Surgeon-General Hamilton, to answer, in the name of my country, the address of the Secretary of State, I accepted with pleasure and so informed, by letter, the Secretary-General. My surprise was, therefore, great and painful when this morning, while inquiring about the order of exercises at the opening of the Congress, the same Surgeon-General Hamilton informed me that he had requested Dr. Semmola, of Naples, to make the answer.

This change was done without my knowledge and consent, and was, therefore, an insult. I am the representative of the Italian Government, inasmuch as I was delegated to this Congress by the Minister of Public Instruction, the only Minister that has authority to make such an appointment. Prof. Semmola's appointment is not from the Government, but from one Minister—that of the Interior—as an expression of personal regard. The plea that he is a Senator of the kingdom should not be considered in this matter, as this is a medical and not a political Congress. In view of the foregoing and of the personal affront, I hereby withdraw from the Medical Congress aforesaid.

FRANCESCA DURANTE.

This episode, however, was finally settled through the earnest efforts of Dr. Hamilton and others. In response to a letter from Dr. Hamilton a note was received from Dr. Durante on Wednesday in which he said : "I thank you for your explanatory and very kind letter and, although I feel that my position as the representative of the Italian government would, under the circumstances, suggest my withdrawal from the Medical Congress, the kind disposition of yourself and of the officers of your committee toward me and my country overcome my sense of offended dignity and lead me to respond to your kindness by remaining and participating in the proceedings of the Congress."

To make the reconciliation more complete it was determined that Dr. Durante should preside at the General Meeting of the Congress on Wednesday, at which Dr. Semmola was to deliver his General Address. On the conclusion of the Address Dr. Durante and Dr. Semmola shook hands very cordially.

WHAT PROMINENT MEN SAY OF THE CONGRESS.—DR. N. S. DAVIS said to a representative of THE MEDICAL NEWS, on Thursday evening, in reply to the inquiry whether he thought the Congress had been a success, that in point of numbers it stood second, if not first.

"But as to its character and the scientific value of its work ?"

"Well, I have seen all the presidents of Sections today, and they each and every one of them report most favorably."

"From your experience of previous Congresses, do you not think there was a conspicuous absence of distinguished foreigners—such men, for instance, as Paget and Gull, and Pasteur and Verneuil, and Virchow and Lister, and others whose names are known all over the world ?"

"Yes, that is so ; but then you must remember that many of those you name are over seventy years of age, and at their time of life, and with their professional duties, a journey across the Atlantic, and such a prolonged absence as is thereby implied, is a very serious matter. Sir James Paget himself told me he feared he would be unable to attend on account of his advancing years. Professor Virchow wrote me that he could not come because of an important conference to be held in Berlin this month, of which he is Chairman of the Committee of Arrangements. I do not remember exactly what that conference was, but it was something combining hygiene with some other subject."

"But what about Neudörfer and Lutaud, of Paris, who were to have been here and to have taken part in the proceedings ?"

"Neudörfer is detained by sickness ; and Lutaud—well, I can't say anything about him."

"Then, on the whole, do you think the delegates compare favorably with those of other Congresses ?"

"Yes, I think so. They are younger men, true, but I understand some very valuable papers have been contributed even by those who did not come. M. Simon, for instance, a very eminent man I am told, has forwarded a most important paper. And you must remember we have had difficulties with regard to the foreign delegates."

"What were those ?"

"I do not care to go into them, but, gentlemen—you could count them on the fingers of your two hands—have written and begged foreign delegates not to come. They said there were factional differences. They even went so far as to say that Washington was unhealthy ; that the weather was very hot, and that typhoid fever was prevailing. Of course, this kept some away."

"How do you think the American reputation for hospitality has been maintained ?"

"That I would rather say nothing about. I have heard many complaints from the foreign delegates that they were not able to get into the White House to see the President and Mrs. Cleveland last night—many such complaints. It was unfortunate, very. I am very sorry it occurred."

"Is there any prospect, do you think, that the Congress will ever meet in the United States again ?"

"Not for twenty years at least. These sessions are only triennial, and it is not likely that Washington's turn will come round again for twenty years, if then."

SECRETARY-GENERAL JOHN B. HAMILTON was asked how many delegates have registered.

"Over twenty-six hundred."

"How many foreigners?"

"Three hundred it is estimated, but I have not the local registration-book at hand."

"Have you been cramped for want of money?"

"Yes."

"If the dissension beginning at New Orleans had not taken place, do you think there would have been a larger contingent of foreign delegates?"

"If there had been no system of general misrepresentation practised by many of those who resigned and followed up by personal solicitation to stay away the attendance might have been larger; as it is, the attendance from transatlantic countries is larger than it was at former Congresses."

"Do you know of any dissatisfaction having been expressed by foreign delegates as to their treatment here?"

"No, on the contrary, see Sir James Grant's speech to-day, on this point."

"What do you think of the scientific aspects of the Congress?"

"They are entirely satisfactory, and will take rank with any former Congress. I can only view with contempt the statements made with evident intent to disgrace America and belittle our guests."

"What about the absence of those American physicians who withdrew from the Congress, and remain away?"

"While their absence is to be regretted, yet the facts show the Congress is entirely successful without them."

DR. UNNA, of Hamburg, being asked "What opinion he had formed of the Congress?" replied:

"I do not think it is of as high a character as those of Copenhagen and London. The discord at home has prevented many foreigners from coming. This discord was so prominently heralded abroad that it became in a measure international. If it had not occurred many Germans would have come, not thirty or fifty, but two hundred. This number would have included the most prominent men of the country. I regret that the leading physicians of America did not overlook the discords when it was too late to reconsider action, and so give to the Congress more of the air of being international. Men like Agnew, Loomis, and others are much missed. My strongest impulse in accepting the vice-presidency, and reading a paper, was to prevent the Congress from dwindling into simply a national affair. I regret that others did not take the same view. The scientific aspect, although not equal to former Congresses, is better than was to be expected under the circumstances. Papers in the Dermatological Section were good for the most part, but the discussions were poor; but such is the case at all Congresses. Socially I have not had much personally to complain of, although I am aware of many deficiencies. I know that many errors have been committed. The arrangements have been poorly announced. On the whole, there is much that is to be regretted."

DR. W. T. LUSK, of New York, was asked what opinion he had formed of the Congress.

He replied, "I have heard some complaints from foreign delegates regarding a want of courtesy on the part of the officers of the Congress. It seems there has been some want of business management, and perhaps a lack of experience on the part of the officials in managing such affairs. They have been too much disposed to regard the foreigners as they would our own people, who are always willing to look after themselves, while a European seems to require some one to take care of him."

"What do you think of the scientific value of the Congress?"

"I believe the volumes of Transactions, when published, will be equal in respect of the papers contained therein, to those of any preceding Congress."

"If the unfortunate dissension which began at New Orleans had not occurred, would not the success of the Congress have been more marked?"

"Well, I must say the presence of prominent members of the profession at the discussions was greatly missed."

Dr. Lusk, who was somewhat unwilling to give his views for publication, also stated that he thought that in the division of papers between the Sections of Obstetrics and Gynecology, the former had been unfairly treated by being deprived of several papers properly belonging to it. For instance, a paper on Cæsarean Section, and another on Extrauterine Pregnancy, had both gone to Gynecology, instead of to the proper section—Obstetrics.

DR. MARIANO SEMMOLA, Professor of Therapeutics in the University of Naples, Italy, was asked his opinion of the present Congress, and replied to the queries addressed to him as follows:

"You have attended other Congresses?"

"Yes, indeed I think I have attended every one."

"What opinion have you formed of the scientific value of the Congress?"

"It is considerably below the average of any of its predecessors."

"Do you think that if the unfortunate dissensions at New Orleans had not taken place that a larger number of distinguished men from Europe would have attended this Congress—such men as Porro, from your own country, and Pasteur, Virchow, Esmarch, Paget, MacCormac, etc.?"

"I have met many, if not all those gentlemen at preceding Congresses, and have no doubt at all that if there had been no quarrel among the profession here, some, if not all of them, would have crossed the Atlantic."

"How did you happen to come yourself?"

"I was assured that the quarrel was a matter that had entirely passed over, and so I came on."

"Have you met many of the Americans whom you expected to see?"

"Very few indeed, and it is a matter of sincere regret to me."

"How have the social aspects of the Congress appeared to you?"

Dr. Semmola smiled at the question, shrugged his shoulders and said: "Well, I have had one or two private invitations, but as for the rest—it does not exist."

"You are not favorably impressed then?"

"No; how can I be?"

NINTH SESSION, WASHINGTON, 1887.

DERMATOLOGY IN ITS RELATION TO GENERAL MEDICINE.

An Address delivered in General Session, September 7, 1887.

BY DR. P. G. UNNA,
OF HAMBURG, GERMANY.

IF a specialist is permitted to speak from this exalted place to the representatives of the medical world in all its branches, and desires to remain within his special domain, properly speaking, *one* subject only, viz., he has the relation of his specialty to general medicine.

The true specialist, he who, from pure enthusiasm for his profession, has left the ordinary path of medical practice can travel only one way. Theoretically, and possibly also practically, instructed in all branches of medical science and art, he will devote his entire life to the double object of planting seeds, gathered from the immense field of general medicine, into his special soil, in order to return gratefully to general medicine his harvest—as a ripe fruit. From this point of view, gentlemen, let us consider to-day, the relations of dermatology to general medicine. Let us lay aside all those trifling external circumstances which ordinarily are advanced as an excuse for the existence of special branches. We will forget that the specialist may and must acquire in his small domain, more extensive knowledge, and greater skill than any one engaged in the entire field of medicine. This circumstance which, with iron necessity, has created specialism, is also the one which forever separates it from general medicine. Let us make use to-day of the pleasant fiction that the specialist is created from the growing and ripening conviction of the eminent physician and naturalist, from the ideal wish to enlarge the boundaries of knowledge of nature. Our eye will be sharpened at once for that which connects it with general medicine forever,—*i. e.*, for the interest which general medicine has, on its part, to desire in future the disconnected special culture of individual branches of science and to favor the same.

I consider my task for to-day accomplished, if I should succeed in convincing you that general medicine, that every practising physician, has a great, an ideal interest in this, that dermatology may be cultivated in a manner far more earnestly and extensively than heretofore, by the greatest possible number of workers; that this young daughter of medicine is worthy of such special attention and favor, and will reward the mother for all the trouble spent in its culture.

Dermatology is indeed a young science, not as if for centuries worthy or unworthy laborers had worked in its structure, too large a number of isolated cases, preliminary systems, and names without number testify this. But considered as a science, dermatology has in the course of the present century, not left the stage of continuous fermentation, of never-ending reconstruction. In vain are dermatologists longing for a place of rest, for quiet development, such as has been accorded to ophthalmology since the labors of such men as Helmholtz, Donders, Gräfe. Every important new fact arising in the field of dermatology is liable to shake the entire structure of the present time, and to remind us of its frailty. And is this science, characterized, in spite of practical success, by theoretical insufficiency and constant changes, to bring to general medicine the promised fruits? I hear the question in astonishment, and yet I must reply: Yes, and how paradoxically it may sound, for this very reason. The causes opposed to the development of dermatology are based upon the same circumstances which in future will become of so much value to general medicine.

In no other branch of medical science are observations made so easily, but also defined with such difficulty, as those presented by the skin. The confusing polyformity of processes manifesting themselves externally is sufficient to explain the slow progress of scientific dermatology. As it is far easier to distinguish the qualities of a fluid when it drips slowly as from a filter, than when flowing *en masse* in an open canal, so the isolated symptoms of a skin disease will readily vanish in the contemplation of the entire field. Investigation of diseases of the kidneys by the examination of the urine, of lung diseases by examination of sputa, of diseases of the digestive tract by examining the evacuations, may be compared to the minute but accurate observation of the water drops in the filter.

Attention is simply directed to variations of symptoms, the knowledge of which is easily obtained, as well a the deductions as to the condition of the internal organs; this does not imply much, yet it is safe. A more thorough knowledge of internal organs we obtain by gradual and successive combination and comparison of large series of single observations, a slower process, but steady and satisfactory, and yet remaining imperfect. What results would, for example, arise from observations made on the kidney in different forms of nephritis, where at present we are reduced to speculative examination of the urine and the results obtained at autopsies! If this were sufficient, many controversies might be decided by simple observation. This hypothesis presupposes, however, that the symptomatology of the organ has already attained the same high degree of perfection as has the examination of the urine; if this had not preceded, if the questions were not already formulated, the surprising manifoldness of the picture would irritate as much as ever-changing symptoms in skin diseases impress most physicians, conveying the very contrary of a clear view.

We now arrive at the conclusion that it would have been better, in the interest of dermatology, if in the study of isolated symptoms, of secretions and excretions, for

example, the entire complex of symptoms had not been exposed. The minor exposition would have been examined by means of the auxiliaries physics and chemistry; many questions would have been suggested and answered speculatively, and the main questions brought to a point, so that by the removal of the veil from all processes, our eye would have been concentrated upon those points where questions of pathology of the skin are involved, and simple observation would decide at once yes or no. Yet this is Utopian. In the diseases of the skin we suffer from an oppressing mass of symptoms and have to contend with them. We have no mechanical filter presenting to us, drop by drop, single facts, we have only a mental one in the eagerly directed attention to a single point, and knowledge penetrating more and more into the finer structures of the skin. We shall overcome, working on step by step, the disturbing influences of the multiform external picture. No organ of the body, except the central nervous organ, which partly represents features of the external skin, exhibits so many topographical differences. One segment of the liver presents, in its external structure the same features as any other one, any section of it presents gall ducts and parenchymatous cells, connective tissue, bloodvessels, and nerves.

Let us examine such a complicated organ as the kidney, or the eye; there we have indeed contrasts of cortex, marrow, papillæ, but they repeat themselves in every segment in the same order. Even the eye, if I may compare it to a mechanism, is, like the kidney, approximately of symmetrical radiary construction. The skin, however, presents, like the central nervous system, only bilateral symmetry, and in each of the symmetrical halves we have large series of regions entirely different in structure: either hairy or hairless, rich or poor in muscle, with thick or thin panniculum, more or less provided with terminal nerve apparatus, such which have both sebaceous and glomeriform glands, and others with glomeriform glands only, with thick or with thin stratum corneum, with perfectly developed papillary layer and without it, with equal or unequal degree of diversibility, with acid or weak alkaline reaction of secretion; the skin of extensor and that of flexor surfaces, free surfaces and others of contact; the *cutis vera* and its appendages. A large series of skin affections is changed through such topographical differences to such a degree that it requires a long study in order to conceive the relationship of such affections.
